1. Definitions

Solvents are compounds that are generally liquid at room temperature and atmospheric pressure; they are able to dissolve other substances without chemically changing them. The liquid mixture formed on dissolving a substance (*solute*) in a solvent is termed a *solution*. The molecules of the solution components interact with one another. Solutions are obtained by mixing liquid, solid, or gaseous components with liquids, the liquid always being termed the solvent. When two liquid components are combined, it is arbitrary which of the two components is considered to be the solvent, and which the solute; the liquid component present in excess is usually termed the solvent. Accordingly, plasticizers that are used for flexibilization in plastics processing and paint production may also be regarded as solvents. Plasticizers differ from solvents, however, with regard to their technological significance. A good plasticizer should have

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_437

a very low volatility and thus permanently affect the dissolved substance. An ideal solvent should, in contrast, have a high volatility, so that it can evaporate as rapidly as possible to leave the dissolved substance (e.g., in a paint film). The boundary between plasticizers and solvents is not clear cut – some high-boiling solvents of very low volatility exert a flexibilizing effect over a prolonged period.

A solvent should generally have the following properties [2];

1) Clear and colorless
2) Volatile without leaving a residue
3) Good long-term resistance to chemicals
4) Neutral reaction
5) Slight or pleasant smell
6) Anhydrous
7) Constant physical properties according to the manufacturers' specification
8) Low toxicity
9) Biologically degradable
10) As inexpensive as possible

Inorganic substances (e.g., hydrogen sulfide, ammonia, sulfur dioxide, hydrogen fluoride, and hydrogen cyanide) that are used as solvents in special applications, mainly at low temperature or under pressure, will not be discussed here.

2. Physicochemical Principles

2.1. Theory of Solutions

During dissolution the solvent acts on the substance to be dissolved to increase its state of distribution. Dissolution results in the formation of real solutions, colloidal solutions, or dispersions depending on the size of the particles that interact with the solvent molecules.

In *real solutions* the diameter of the dissolved particles is ca. 0.1 nm, and is thus of the order of magnitude of the free molecules. Real solutions are formed by most inorganic and organic compounds of low molecular mass. They are clear, physically homogeneous liquids.

In *colloidal solutions* the diameter of the dissolved particles is ca. 10 – 100 nm. Colloidal solutions are generally clear to weakly opalescent liquids, but exhibit inhomogeneities as regards some physical properties (e.g., the Tyndall effect).

In *dispersions* the diameter of the particles is larger than in colloidal solutions. Dispersions are turbid to milky liquids consisting of at least two phases.

Intermolecular Forces. During the dissolution of a substance (A) in a solvent (B) the forces of attraction between the molecules of the pure components ($K_{\mathrm{A-A}}$ and $K_{\mathrm{B-B}}$) are destroyed, and new forces are simultaneously formed between the solvent and substance molecules:

$$K_{\mathrm{A-A}} + K_{\mathrm{B-B}} \longrightarrow 2\,K_{\mathrm{A-B}}$$

A substance is generally readily soluble in a solvent if the forces of attraction in the pure substance are of the same order of magnitude as the forces of attraction in the pure solvent. A substance is generally insoluble in a solvent if the forces of attraction between its molecules are significantly higher or lower than in the pure solvent. In this case more energy is required to overcome the forces of attraction in the pure components than is released on formation of the solution. This is the explanation of the rule of thumb "Like dissolves like" (*similia similibus solvuntur*). The intermolecular forces of attraction differ – they are strongest in crystalline solids, weaker in amorphous solids and liquids, and weakest in gases. Intermolecular forces are classified according to their physical nature (Table 1) [3–6].

Table 1. Intermolecular forces

Type of force	Interaction between	Temperature dependence
Ionic	ions	weak
Ion–dipole	ions and dipoles	weak
Directional	permanent dipoles	strong
Induction	permanent and induced dipoles	weak
Dispersion	atomic dipoles	weak
Hydrogen bonds	groups of molecules	strong

Ionic (Coulomb) Forces. Forces of attraction between ions of opposite charge are termed ionic or Coulomb forces. The force with which two ions 1 and 2 attract one another depends on their electrical charges e_1 and e_2 and the distance r between them:

$$K_{\mathrm{II}} \approx -\frac{e_1 \cdot e_2}{r^2}$$

Coulomb forces are responsible for the stability of ionic crystals (e.g., NaCl). When such a compound is dissolved in a polar solvent (dipole moment μ), dissociation and simultaneous solvation of the ions occur. The force of attraction between the ions is now inversely proportional to the dielectric constant of the solvent, and is thus reduced. New ion – dipole forces are formed as a result of the attraction of the permanent dipoles of the solvent by the ions:

$$K_{\mathrm{ID}} \approx -\frac{e_{\mathrm{I}} \cdot \mu}{r^3}$$

The distance between the solvated ions in the solution generally changes only slightly with temperature and depends on the thermal expansion coefficient of the solution. The forces between the ions are therefore only slightly temperature dependent.

Dipole – Dipole Forces. Dipole – dipole (directional) forces are forces of attraction between molecules with a finite, permanent overall dipole moment. The forces of attraction resulting from the dissolution of a polar molecule (μ_1) in a polar solvent (μ_2) are given by [7]:

$$K_{\mathrm{DD}} \approx -\frac{\mu_1 \cdot \mu_2}{r^4}$$

The distance between the dipoles depends largely on the position of the poles in the molecule (i.e., on steric molecular influences) and on thermal vibrational movements. The force of attraction between the dipoles accordingly decreases sharply with increasing temperature.

Induction forces are produced as a result of interactions between permanent dipoles and induced dipoles. The electric field of a molecular dipole leads to charge displacement in the neighboring molecule and thus to the induction of a dipole.

The magnitude of the induced dipole moment μ_{ind} depends on the magnitude of the permanent dipole moment μ and on the polarizability α of the second molecule [8]. Induction forces are only slightly temperature dependent:

$$\mathrm{K}_{\mathrm{DDi}} \approx -\frac{\alpha \cdot \mu^2}{r^7}$$

Dispersion (London – Van der Waals) Forces. Dispersion forces are formed by mutual induction of atomic dipoles due to the electromagnetic field between the nucleus and electrons of the atom.

Dispersion forces therefore depend on the displaceability of the electrons in the atoms, the polarizability α, and the availability of the electrons, i.e., on the ionization potential *IP* [9]:

$$K_{\mathrm{Dis}} \approx -\frac{\alpha^2 \cdot IP}{r^7}$$

Since charge displacement is independent of the thermal motion of the particles, dependence of the dispersion forces on temperature is weak over the distance between the attracting partners. Dispersion forces act in all atoms and molecules.

Hydrogen Bonds [10–14]. Hydrogen bonding forces exist in substances that have hydroxyl or amino groups (e.g., water, alcohols, acids, glycols, and amines). These molecules act as hydrogen donors and thus form a bond with hydrogen acceptors (e.g., esters and ketones). Water, alcohols, and amines act both as hydrogen donors and acceptors. Very weak hydrogen bonds also exist in halogens and sulfur. Hydrogen bonds are highly dependent on the mutual orientation of the molecules and thus on the temperature.

Thermodynamic Principles [15]. Forces of attraction act between the molecules of the pure components and between the different molecules in the solution. If the forces of attraction in the solution are greater than those in the pure components, dissolution is accompanied by a decrease in the internal energy of the system. The process is exothermic and heat is released. If, however, the forces of attraction between the molecules of the pure components are greater than those in the solution, the internal energy of the system is increased with absorption of heat. In a closed system, this endothermic dissolution process is accompanied by cooling. In open systems heat is absorbed from the surroundings.

Most dissolution processes are endothermic and are thus promoted by a temperature increase: the solubility has a positive temperature coefficient. Exothermic dissolution processes have a

negative temperature coefficient (i.e., the solubility decreases with rising temperature). Miscibility gaps frequently occur above certain temperatures (Fig. 1).

Figure 1. Miscibility gap for mixtures of butyl glycol and water at atmospheric pressure

Why do endothermic dissolution processes occur spontaneously? The Gibbs – Helmholtz equation provides the answer:

$$\Delta G = \Delta H - T\Delta S$$

The reaction enthalpy ΔH is negative in exothermic processes, and positive in endothermic processes. The reaction entropy ΔS, which is a measure of the change in the state of disorder of the system, is always positive since the entropy of the solution (mixture) is always greater than that of the pure components.

The Gibbs free energy ΔG must be a negative quantity in all spontaneously occurring processes. In exothermic processes ΔH is negative: dissolution occurs spontaneously with release of heat, and is "enthalpy determined." In endothermic processes ΔH is positive; these processes also proceed spontaneously, but the temperature of the system falls. On account of the large positive reaction entropy the negative contribution $-T\,\Delta S$ exceeds the positive reaction enthalpy ΔH, and ΔG is again negative. The process is "entropy determined." If, however, ΔH is positive and greater than $T\,\Delta S$, no dissolution takes place: the system remains heterogeneous.

Dilution processes are used very often, for example in the paint industry, and are always entropy-determined [16].

Systems with a negative temperature coefficient of solubility are mainly enthalpy-determined. The interaction between the partners is often due to weak hydrogen bonds, which become weaker than the forces between the pure components on increasing the temperature. The result is a decrease in solubility. Examples of enthalpy-determined systems with a negative temperature coefficient are summarized in Table 2.

Table 2. Aqueous solution systems with a negative temperature coefficient of solubility

Solvent	Solubility in water	g/100 g
Methyl butyl ether	1.5 (10 °C)	0.9 (25 °C)
2-Methylfuran	18.2 (10 °C)	13.9 (25 °C)
Isoamyl alcohol	2.6 (22 °C)	2.2 (36 °C)
Ethyl acetate	10.0 (0 °C)	7.7 (25 °C)
Butyl glycol	∞ (40 °C)	11.0 (60 °C)

The change in the total energy of the system can thus be negative or positive. This change in energy is termed heat of solution or mixing, or solution or mixing enthalpy [17], [18].

Systems that are miscible with one another without any change in temperature are termed athermic systems [19], [20]; they include the following solvent pairs:

Benzene – trichloromethane
Bromobenzene – chlorobenzene
Methanol – ethanol
Toluene – tetrachloromethane
Methyl acetate – ethyl acetate
Aniline – water

Negative heats of mixing (i.e., warming of the system) are found in the following solvent pairs:

Water – acetone
Water – methanol
Water – propanol
Trichloromethane – acetone

Positive heats of mixing (i.e., cooling of the system during mixing) occur with the following solvent pairs:

Trichloromethane – carbon disulfide
Acetone – carbon disulfide
Gasoline – carbon disulfide

Cohesive Energy Density and Solubility Parameters. As a result of attractive or cohesive forces the molecules in pure solvents have a cohesive energy that has to be expended in molecular separation processes (e.g., dilution, evaporation, or addition of another substance). The cohesive energy can be calculated from the enthalpy of vaporization ΔH_V and the work that is required to expand the vapor against the atmosphere (volume work) [21]. The cohesive energy per unit volume, i.e., the *cohesive energy density*, is defined as [17], [22], [23]:

$$e = \frac{(\Delta H_V - RT)}{V}$$

The cohesive energy density e is a specific temperature-dependent parameter for each solvent and represents a direct thermodynamic measure of the forces of attraction in solvents. It can be used to evaluate the solvency of the solvents if the cohesive energy densities of the substances to be dissolved are also known.

The cohesive energy density of a solvent A is altered when it is mixed with another solvent B. Two interaction pairs A – B are formed from each interaction pair A – A and B – B. The new cohesive energy density of the pair A – B in solvents of very low polarity being approximately equal to the geometric mean of the cohesive energy densities of the pure components [17], [22], [24–26]:

$$e_{AB} = (e_{AA} \cdot e_{BB})^{1/2}$$

The square root of the cohesive energy density is termed the *solubility parameter* δ. It is also a measure of the intermolecular forces in pure substances. Solvents with comparable solubility parameters have similar interaction forces and are therefore readily miscible and mutually soluble. In order to take account of not only the dispersion forces but also of the polar forces and hydrogen bonds, the solubility parameter is resolved into the following components [27], [28]:

$$\delta^2 = \delta_D^2 + \delta_P^2 + \delta_H^2$$

If the three solubility parameter components for dispersion forces δ_D, dipole forces δ_P, and hydrogen bonds δ_H are plotted on a three-dimensional space diagram (Fig. 2), a system is obtained in which a vector $\rightarrow \vec{\delta}$ is defined for each solvent. The vector describes the solvent's solubility and miscibility behavior [29], [30]. Solvents that lie close to one another in this space diagram (i.e., whose vector difference $\Delta\delta$ is small) have similar solution properties and often a similar chemical structure. Solvents that are far apart on the diagram differ greatly in their chemical and physical characteristics; they are generally immiscible [31–33]. The solubility parameters as well as their components are shown for some solvents in Table 15.

Figure 2. Solubility parameter diagram
S_1 = solvent; S_2 = non-solvent; M = solvent mixture

The predictions that can be made for solvent mixtures on the basis of the solubility diagram are not strictly valid because they involve thermodynamic simplifications and empirical parameters, and disregard temperature effects [30], [34]. A strong warning must therefore be given against the uncritical use of solubility parameters. Nevertheless, description of the solvents with the aid of the solubility parameter concept often provides useful information about their solvency and reveals similarities which can otherwise only be characterized empirically (e.g., latent solvents or dilutability).

Solvent Miscibility. As a rule solvents are readily miscible if the difference in their solubility parameters $\Delta\delta$ is $\leq 4-6$ units. Solubility is generally limited if the differences are larger (Table 3).

In the case of strongly polar (ionic) forces or hydrogen bonds, the solubility parameter con-

Table 3. Miscibility of solvents as a function of the difference in solubility parameters $\Delta\delta$

Solvent A	Solvent B	$\Delta\delta$, $(J/cm^3)^{1/2}$	Miscibility
Butyl acetate	methyl isobutyl ketone	0.2	good
Ethyl glycol acetate	xylene	0.2	good
Tetrachloroethylene	xylene	1.0	good
Ethanol	butanol	2.7	good
Methanol	dimethyl sulfoxide	3.3	good
Ethylene carbonate	dimethyl sulfoxide	3.7	good
Methyl glycol	hexane	7.2	poor
Cyclohexane	dimethyl sulfoxide	9.6	poor
Hexane	methanol	14.8	moderate

cept is of limited applicability. For example, the following pairs of solvents are only partially miscible despite the small difference in their solubility parameters:

Nitromethane – ethyl glycol	3.5
Ethanol – methyl iodide	2.0
Decane – nitrobenzene	4.7
Ethanol – naphthalene	5.9

On the other hand, many solvent pairs are readily miscible although the difference between their solubility parameters is large:

Dimethyl sulfoxide – benzene	7.6
Nitromethane – tetrachloromethane	8.2
Dimethylformamide – hexane	9.9
Benzene – methanol	10.9
Ethanol – hexane	11.1
Methanol – tetrachloromethane	12.1
Ethylene carbonate – butyl acetate	12.7
Water – acetone	27.4
Water – tetrahydrofuran	28.7

In some cases the resolution of the solubility parameter into the three components δ_D, δ_P, and δ_H [32], [33], [35] is more suitable for explaining the experimental facts. For example, although the difference between the solubility parameters of the partially miscible solvent pair nitromethane – ethylene glycol is indeed small ($\Delta\delta = 3.5$), both solvents differ greatly as regards their solubility parameter δ_H ($\Delta\delta_H = 22.0$). Many empirical results (e.g., the good miscibility of benzene and methanol) cannot, however, be explained by this approach.

Solubility of Polymers [36–43]. Most polymers are readily soluble if their solubility parameters are comparable to those of the solvent in question. The upper limit for good solubility is a difference in the solubility parameters of 6 units (Table 4). The following selected systems are not, however, mutually soluble despite the small solubility parameter difference $\Delta\delta$:

Poly(vinyl chloride) – trichloromethane	1.6
Poly(vinyl chloride) – toluene	2.5
Polystyrene – heptane	2.9
Poly(vinyl acetate) – hexane	4.3
Poly(vinyl acetate) – diethyl ether	3.7
Cellulose – dimethyl sulfoxide	5.3

Furthermore, poly(vinyl acetate) is readily soluble in methanol and amylose is readily soluble in water, even though the differences in the solubility parameters are large ($\Delta\delta = 9.8$ and 22.5 units, respectively).

2.2. Dipole Moment, Polarity, and Polarizability

In order to describe their solubility properties, solvents are often subdivided according to their polarity, i.e., polar and nonpolar solvents. Since the term polarity cannot be defined unambiguously in physical terms, such a classification is not meaningful. The term polarity includes parameters such as dipole moment, hydrogen bonding, polarizability, entropy, and enthalpy. The dipole moment μ of a substance is a molecular property resulting from the vector sum of bond-dipole moments. Highly symmetrical molecules (e.g., tetrachloromethane and benzene) accordingly have no dipole moment; other aromatic hydrocarbons and dioxane exhibit only very small dipole moments. Less symmetrical molecules with strong bond dipoles have dipole moments between 1.6 and 1.9 D (alcohols, esters, glycol ethers), glycols and ketones have higher values (2.3 – 2.9 D). The solvents with

Table 4. Miscibility of polymer–solvent pairs as a function of the difference in solubility parameters $\Delta\delta$

Polymer	Solvent	$\Delta\delta$ $(J \cdot cm^3)^{1/2}$	Miscibility
Polyacrylonitrile	ethylene carbonate	0.6	good
Polystyrene	ethyl acetate	0.8	good
Poly(vinyl chloride)	tetrahydrofuran	1.5	good
Polyisobutene	hexane	1.5	good
Polyacrylonitrile	dimethylformamide	4.9	good
Poly(vinyl acetate)	ethanol	7.0	moderate
Polyisobutene	ethanol	9.8	poor
Polystyrene	methanol	11.0	poor

the largest dipole moments (3.7 – 5.0 D) are ethylene carbonate, nitropropane, dimethylformamide, and dimethyl sulfoxide (Table 15).

The dissolution behavior of a solvent cannot be predicted solely on the basis of its dipole moment. For example, dioxane ($\mu = 0.4$ D) is a very good solvent and has a comparable solvency to dimethyl sulfoxide ($\mu = 4.0$ D).

Dipole–dipole and induction forces in solvents or solutions decrease with increasing molecular mass of the solvent [44]. Since this effect is not reflected in the dipole moment of the solvent, a polarizability parameter P is used to describe the dipole – dipole interaction forces [35]. This parameter can be calculated from the ionization potential IP, polarizability α, and dipole moment μ [45]:

$$P = \frac{2\mu^4}{3k \cdot T \cdot \varepsilon}$$

where $\varepsilon \approx \alpha \cdot IP$.

The dipole moment μ is also used in conjunction with the solubility parameter δ as a coordinate in solubility diagrams to take account of the influence of variations in polarity [45–47].

The polarizability α of an electrically neutral compound is a measure of the displaceability of charge carriers within the molecule. The greater the polarizability, the stronger are the dipoles in duced by an external electromagnetic field; the magnitude of the polarizability and strength of the dispersion forces are thus related to one another.

2.3. Hydrogen Bond Parameters [48]

The strengths of hydrogen bonds in solvents have been divided into three classes [49–53]:

1) Solvents with weak hydrogen bonding (hydrocarbons, chlorinated hydrocarbons, nitro compounds, nitriles)
2) Solvents with moderately strong hydrogen bonding (ketones, esters, ethers, aniline)
3) Solvents with strong hydrogen bonding (alcohols, carboxylic acids, pyridine, water, glycols, amines)

This classification allows solvents to be described in terms of their solvency for polymers by means of solubility parameters, and also permits hydrogen bond forces to be taken into account. This is done by determining the solubility limits of the polymer in solvents belonging to each of the three classes. Three solubility parameter regions for a polymer are thus obtained. Attempts have also been made to use corrections to take account of the variations in solubility parameters caused by hydrogen bonding [54–57].

The hydrogen bond parameters γ provide a relatively accurate, simple characterization of solvents that can form hydrogen bonds [58], [59]. The parameter (Table 15) is determined from the shift of the oxygen – deuterium vibration frequency in the IR spectrum obtained when deuteromethanol is dissolved in the relevant solvent.

Solvents that undergo hydrogen bonding may act as proton donors or acceptors [10], [48]:

1) Proton donors (e.g., trichloromethane)
2) Proton acceptors (e.g., ketones, esters, ethers, aromatic hydrocarbons)
3) Combined proton donors and acceptors (e.g., alcohols, carboxylic acids, primary and secondary amines, water)
4) No hydrogen bonding (e.g., aliphatic hydrocarbons)

No hydrogen bonds exist in solvent mixtures comprising solely proton acceptors; hydrogen bonds are only formed in the presence of a proton donor and result in an increase in miscibility [48], [60].

2.4. Solvation

When a substance (solute) is dissolved in a solvent or solvent mixture, the forces of attraction between the solute molecules decrease because the solvent molecules penetrate between the solute molecules and finally surround them as a layer. This process, termed solvation, results in distribution of the solute in the solution at a molecular level. The strength of the solvation forces and the number of solvent molecules in the solvation layer depend on the solubility parameter, dipole moment, hydrogen bonding, polarizability, and the molecular size of the solvent and solute. The number of solvent molecules in a solvent – solute complex is determined by the degree of solvation β. Values for cellulose nitrate – ketone systems are given in Table 5 [61]. The degree of solvation β increases as the size of the solvent molecule decreases. It also increases with increasing solubility parameter δ. In the cellulose nitrate – ketone systems, hydrogen bond forces and dipole forces have little influence because both the binder and the solvent molecules are proton acceptors, and few hydrogen bonds are formed. Furthermore, the dipole moments of the solvents are roughly equal. In other cases, however, hydrogen bonding and dipole moments can greatly influence the degree of solvation.

Table 5. Connection between molecular mass of ketone solvents M, degree of solvation (for cellulose nitrate) β, solubility parameter δ, hydrogen bond parameter γ, and dipole moment μ

Solvent	M	β	δ	γ	μ
Methyl amyl ketone	114.18	1	8.5	7.7	2.7
Methyl propyl ketone	86.13	3	8.9	8.0	2.7
Methyl ethyl ketone	72.12	7	9.3	7.7	2.7
Acetone	58.08	12	10.0	9.7	2.9

2.5. Solvents, Latent Solvents, and Non-Solvents

True (active) solvents dissolve a given substance at room temperature; the solubility parameters of the solvent and the solute are similar.

Latent solvents cannot dissolve a substance by themselves. They can, however, be activated by adding a true solvent or a non-solvent. Latent solvents include solvents with extremely high or low solubility parameters or hydrogen bond parameters, such as alcohols, water, acetals, higher molecular mass esters, or ketones. In the solubility parameter space diagram, the latent solvents lie outside the solubility regions of the substances to be dissolved. On mixing with true solvents or non-solvents, mixed solvents are obtained whose solubility parameters fall in the region of the substances to be dissolved (Fig. 2).

Non-solvents are unable to dissolve the substance in question. Their solubility parameters and hydrogen bond parameters lie outside the solubility regions of the substances to be dissolved.

The expressions solvent, latent solvent, non-solvent only apply to a specific substance to be dissolved. A solvent can be a non-solvent for another substance and *vice versa*.

2.6. Dilution Ratio and Dilutability

If a non-solvent is added dropwise to a cellulose nitrate solution, the cellulose nitrate eventually separates as a precipitate or gel. The volumetric ratio of non-solvent to solvent that is still tolerated in the solution is termed the *dilution ratio*. The dilution ratio is an empirical, dimensionless quantity that provides information on the solvency of a solvent or solvent mixture. In order to determine the dilution ratio toluene or butanol is used as the diluent (non-solvent).

Table 6 shows the dilution ratios for various diluents and solvents. As a rule the dilution ratio decreases with increasing boiling point of the solvent; however, the solvent of lowest molecular mass in a homologous series (e.g., methanol, methyl acetate, methyl glycol) often behaves differently.

Mixtures of two solvents frequently have a higher dilution ratio than the pure components: ether – alcohol and toluene – ethanol mixtures are better solvents for cellulose nitrate than any of the pure solvents; ethyl acetate and butyl acetate are better solvents for cellulose nitrate – synthetic resin combinations if they contain a proportion of ethanol or butanol, respectively. The solubility parameters of the mixed solvents are more comparable to those of the binder than those of the pure solvents.

Table 6. Dilution ratios for cellulose nitrate

Solvent (volume ratio)	Diluent (non-solvent)			
	Toluene	Xylene	Aliphatic hydrocarbon	Butanol
Methyl acetate	3.0		0.9	
Ethyl acetate	3.4	3.3	1.0	8.4
Propyl acetate	3.0	2.0	1.2	
Butyl acetate	2.7	2.7	1.5	8.2
Ethyl glycol acetate	2.5	2.5	1.0	7.5
Acetone	4.5	3.9	0.6	7.0
Methyl ethyl ketone	4.5	3.3		
Methyl isobutyl ketone	3.5	3.7		
Cyclohexanone		7.5	1.0	
Methyl glycol	4.7	2.9	0.2	
Ethyl glycol	5.0	4.7	1.0	6.9
Butyl glycol	4.0	3.2	2.3	
Methanol	2.5	2.0	0.3	
Butyl acetate/butanol (9/1)	3.5			
Butyl acetate/butanol (5/5)	5.5			
Methyl ethyl ketone/ethanol (85/25)	5.0			
Ethyl acetate/ethanol (1/1)	3.5			

The temperature dependence of the dilution ratio is shown in Table 7. The solvency of solvents consisting of small molecules increases with increasing temperature, whereas solvents consisting of large molecules behave in the opposite way. In other experiments, the dilution ratio generally decreases with increasing temperature, as has been demonstrated in cellulose nitrate solutions in butyl acetate, ethyl glycol, and methyl isobutyl ketone. The reason for this is that a cellulose nitrate solution adopts the gel state with a rise in temperature. The gel reverts reversibly to the liquid state when the temperature is lowered. However, for thermodynamic reasons the solvency of a solvent always increases with rising temperature. There is thus no meaningful connection between the dilution ratio and solvency of a solvent.

Table 7. Dependence of the dilution ratio on temperature (solute = cellulose nitrate; diluent = toluene)

Solvent	−10 °C	20 °C	50 °C
Ethyl acetate	2.48	2.58	2.62
Butyl acetate	2.74	2.70	2.61
Amyl acetate	2.66	2.52	2.26
Octyl acetate	1.85	1.74	1.44

As expected, the dilution ratio falls with rising cellulose nitrate concentration in the solution (Table 8).

Table 8. Concentration dependence of the dilution ratio of cellulose nitrate solutions in butyl acetate

Cellulose nitrate, g	Butyl acetate, mL	Toluene, mL	Dilution ratio
1.0	20	75	3.75
2.0	20	71	3.55
3.0	20	67	3.35
4.0	20	63	3.15

The dilution ratio reveals some similarities between the solvency of different solvents. However, most measurements are restricted to cellulose nitrate, and extrapolation of the results to other binders seldom provides correct results. Furthermore the dilution ratios, unlike solubility parameters, are unable to explain several phenomena (e.g., the enhancement of the solvency of a solvent produced on adding a non-solvent).

The apparent or theoretical *dilutability* denotes the dilution ratio that just results in a saturated solution. The true or practical dilutability predicts that this solution to which diluent has been added can still be applied satisfactorily, for example in the paint sector clear varnish films can form from these solutions after drying.

The limiting concentrations in a ternary system can be represented not only by a space diagram, but also by a three-coordinate system in the form of an equilateral triangle (Fig. 3).

The corners of the triangle represent the pure (100 %) solvents A, B, and C. The point X on

the side A – B gives the composition of a solvent mixture comprising B – X % of solvent A and A – X % of solvent B. The composition of a point P within the triangle can be determined by constructing perpendicular lines from P onto the sides of the triangle to obtain the points of intersection a, b, and c. The lengths P – a, P – b and P – c give the percentage contents of the solvents A, B, and C, respectively.

The sum of these lengths is taken as equal to 100 %. Solubility regions can thus be determined in ternary systems by measuring the quantitative miscibility of the solvent A on dilution with solvents B and C or B – C mixtures.

Figure 3. Triangular coordinates for determining the composition of a ternary mixture of solvents A, B, and C (for description, see text)

2.7. Influence of Molecular Mass on Solubility

The solubility of chemically related compounds decreases with increasing molecular mass since the intermolecular forces of interaction increase. For example, benzene is completely miscible with ethanol, whereas anthracene and ethanol are only partially miscible. The influence of molecular mass on solubility is particularly evident in macromolecules. For example, alcohol, acetone, and acetic acid readily dissolve styrene, but not polystyrene; vinyl acetate dissolves in saturated hydrocarbons and ether, whereas poly(vinyl acetate) does not. Cellulose is insoluble in alcohols, poly(ethylene glycol) is insoluble in ethers, poly(vinyl chloride) is insoluble in vinyl chloride, and polyacrylonitrile is insoluble in acetonitrile, even though good solubility would be expected on account of the chemical relation between the polymers and monomers.

On account of their very large molecular mass, highly cross-linked polymers do not dissolve in solvents, even at elevated temperature. They are, however, swollen by solvents depending on the nature and density of the cross-linking sites [62], [63].

2.8. Dissolution and Solution Properties

Rate of Dissolution. Section 2.1 dealt with the thermodynamic equilibrium between the solvent and substance to be dissolved; the mixing time was disregarded. Dissolution proceeds, however, at a finite rate which depends on the specific surface area of the substance to be dissolved, its degree of crystallisation, its rate of diffusion into the solvent, and on the temperature. Often a substance is considered to be sparingly soluble if its rate of dissolution is low. This assumption is, however, incorrect [64].

Miscibility Gap. Some solvent pairs are miscible with one another in all proportions only above or below a critical dissolution temperature. The region in the concentration – temperature diagram in which both partners are immiscible with one another is termed a miscibility gap [17], [65], [66] (Figs. 1 and 4). Hexane and nitrobenzene are completely miscible only above 19.5 °C (Fig. 4 A). Other systems with an upper critical dissolution temperature include:

Aniline – water (168 °C),
2-Chlorobenzoic acid – water (126.2 °C),
Water – phenol (68.8 °C)
Hexane – aniline (65.9 °C)
Cyclohexane – methanol (45.6 °C)

Systems with a lower critical dissolution temperature include:

Triethylamine – water (17 °C, Fig. 4 B)
Ethylpiperidine – water (7.5 °C)

Systems with an upper and lower critical dissolution temperature include nicotine – water (60 and 218 °C, Fig. 4 C).

The miscibilities of various solvents with water are given in Table 16.

Figure 4. Two-phase solvent systems with miscibility gaps

Physical Properties of Mixtures. The physical properties of an ideal mixture (e.g., vapor pressure) are obtained from the arithmetic mean of the properties of the individual components. In most mixtures, however, behavior is not ideal and the vapor pressure is greater or less than the sum of the values of the components. The reason for this is that the interaction forces in the pure components are different from those in the mixture. If the molecular forces of interaction in the pure components are lower than in the mixture, the vapor pressure of the mixture is lower than the sum of the pressures of the components (e.g., acetone – trichloromethane). In most cases, however, the forces of interaction in the pure components are higher than in the mixture, with the result that the vapor pressure increases on mixing (e.g., benzene – ethanol).

Similar variations in the densities and surface tensions of mixtures are also known. The density of a mixture of bromo- and chlorobenzene is equal to the arithmetic mean of the densities of the individual components, whereas the density of trichloromethane – diethyl ether is about 1.5 % above the mean value. The surface tensions of the systems diethyl ether – benzene and benzene – carbon disulfide are equal to the calculated values. The surface tension of methanol – ethyl iodide is greater and that of benzene – ethanol and acetone – carbon disulfide are less than the calculated values.

Azeotropes. Molecular associations between the components of a mixture can result in systems that have a constant boiling point at a given concentration. The boiling point may be lower or higher than that of the individual components. Such mixtures are termed azeotropic mixtures or azeotropes. Low-boiling and high-boiling mixtures are denoted as minimum or maximum azeotropes, respectively. Examples of low-boiling azeotropes [67], [68] are benzene – water (*bp* 69.4 °C) and benzene – ethanol (*bp* 67.8 °C). Acetone and chloroform form a high-boiling azeotrope (*bp* 64.7 °C).

The composition of the liquid phase of the azeotrope is the same as that of the vapor phase with which it is in equilibrium. It depends on temperature and pressure, and azeotropically boiling mixtures are not necessarily azeotropically evaporating mixtures. However, azeotropically evaporating mixtures often form even at room temperature; their composition differs from that of the azeotropically boiling mixtures. Azeotrope formation can be suppressed by lowering the boiling point (vacuum distillation) and the components can then be separated if the vapor pressures of the pure components respond differenly to a change in temperature. This is always the case if the heats of vaporization of the pure components differ widely.

The formation of low-boiling azeotropes is a fortunate phenomenon for the paint technologist

because water and solvents then evaporate more rapidly than usual (azeotropes, see Table 17). However, these azeotropic mixtures also have several disadvantages:

1) The flash point is lower
2) The explosion limit is lower
3) The higher evaporation rate may have a negative effect on the paint surface
4) Paint flow may be poor because the azeotropic mixture constantly evaporates

Systems Containing More Than Two Components. As in binary systems, the behavior of systems containing more than two components can be understood on the basis of intermolecular forces and solubility parameters. Water and tetrachloromethane have widely differing solubility and hydrogen bond parameters, and are therefore immiscible. Added acetone dissolves partly in the aqueous phase due to hydrogen bond formation, and partly in the tetrachloromethane phase due to dispersion and induction forces. Twice as much acetone dissolves in the aqueous phase as in tetrachloromethane. On increasing the acetone concentration a homogeneous solution is obtained. The added solvent thus acts as a *solubilizer* for the two immiscible solvents.

Solvents having average solubility and hydrogen bond parameters are generally suitable as solubilizers, particularly ketones and glycol ethers. Butyl glycol, diglycol, and triglycol are often used because they contain hydrophilic and hydrophobic groups which effect miscibility between partners having widely differing solubility and hydrogen bond parameters. Very small amounts of a solubilizer are often sufficient to homogenize a heterogeneous solvent mixture. The two-phase system comprising hexane and methanol (mass ratio 2 : 1) is rendered homogeneous by adding 0.5 wt % dichloromethane.

Addition of solvents as solubilizers is important in the dissolution of polymers. Poly(vinyl acetate) is insoluble in pure ethanol, but dissolves fairly readily in ethanol containing 3 % water. Cellulose triacetate is sparingly soluble in pure trichloromethane, but is readily soluble in trichloromethane containing 3 % methanol. Many paint resins dissolve more readily in aromatic-containing naphtha fractions than in pure naphtha. Poly(vinyl chloride) is sparingly soluble in acetone and carbon disulfide, but is more readily soluble in a mixture of the two solvents.

3. Physical and Chemical Properties

see Tables 23 and 24.

3.1. Evaporation and Vaporization

Solvents are classified according to their boiling point ranges into:

1) Low boilers: $bp < 100\,°C$
2) Medium boilers: bp 100 – 150 °C
3) High boilers: $bp > 150\,°C$

The boiling point of a liquid is defined as the temperature at which the vapor pressure of the liquid reaches 101.3 kPa. Thermal energy is consumed in the evaporation of a liquid and is extracted from the surroundings, resulting in cooling.

A knowledge of the boiling point ranges of solvents is important in distillation and extraction processes. However, in the paint and adhesive sectors a knowledge of solvent volatility below the boiling point is more important. Below the boiling point the liquid is in equilibrium with its vapor, the vapor pressure p_s is < 101.3 kPa and is determined from the vapor pressure curve according to the Clausius – Clapeyron equation (integrated form):

$$\ln p_S = A - \frac{\Delta H_V}{RT}$$

where A is a general constant, ΔH_V the molar enthalpy of vaporization, R the gas constant, and T the absolute temperature. The higher the temperature, the greater the vapor pressure (Fig. 5); ΔH_V increases with increasing boiling point of the solvent according to the Pictet – Trouton rule:

$$\frac{\Delta H_V}{T_S} = \text{constant}$$

where T_S is the absolute boiling point.

There is no general correlation between the evaporation rates and boiling points of solvents. Solvent volatility generally decreases with increasing boiling point if the solvents are chemically related [69]. Solvents that tend to form hydrogen bonds (e.g., water, alcohols, amines) are less volatile than other solvents with the same boiling point since energy has to be supplied to rupture the hydrogen bonds before the transition to the vapor state occurs. The evaporation rate w of solvents is obtained empirically according to the Knudsen equation [70], [71]:

$$w = K P_V \sqrt{\frac{2\pi RT}{M}}$$

where the transmission coefficient $K \approx 1$, P_V is the vapor pressure, M is the molecular mass, and ω is expressed in g/cm^{-2} s^{-1}.

The evaporation rate of solvents depends on:

1) Vapor pressure at the processing temperature
2) Specific heat
3) Enthalpy of vaporization
4) Degree of molecular association
5) Rate of heat supply
6) Surface tension
7) Molecular mass of the solvent
8) Atmospheric turbulence
9) Atmospheric humidity

Since these factors all depend on one another, it is impossible to give a theoretical prediction of the rate of evaporation [70–76]. In practice, the evaporation time of a given amount of solvent is determined experimentally under identical external conditions and compared with that of diethyl ether, or in some countries with that of butyl acetate.

The results are termed *evaporation numbers* (Table 9) and are referred to diethyl ether = 1. Evaporation numbers are listed in Table 24.

Solvents can be subdivided into four groups on the basis of their evaporation numbers:

1) High volatility: < 10
2) Moderate volatility: 10 – 35
3) Low volatility: 35 – 50
4) Very low volatility: > 50

A similar volatility classification of solvents is adopted in the United States with butyl acetate = 1 being chosen as the reference:

Class 1: rapid evaporation, > 3.0
Class 2: moderate evaporation, 0.8 – 3.0
Class 3: slow evaporation, < 0.8

If a substance with a relatively high molecular mass is dissolved in a solvent, its rate of evaporation decreases [77–80]. Solvents evaporate more rapidly from cellulose ester and cellulose ether solutions than from polymer or resin solutions. The volatility of a solvent in a polymer film depends on the difference between the solubility parameters of the solvent and the polymer. The polymer occupies a certain space in the solubility parameter diagram with coordinates δ_D, δ_P, and δ_H. Solvents that can dissolve the polymer are situated outside it (see Fig. 2). A solvent whose parameter lies close to the center of the polymer solubility space interacts strongly with the polymer; the solvent therefore evaporates slowly from the drying polymer film, and may even be retained. Solvents that interact weakly with the polymer are situated at the boundary of the polymer solubility space (i.e., in the transition region between solvents and non-solvents) and therefore evaporate more readily from the polymer film [33].

Solvents should not only evaporate rapidly after the application of a paint film, but should also promote the formation of a coating as follows:

1) Prevent blushing and absorption of condensed water vapor from the atmosphere, which is formed as a result of cooling due to solvent evaporation
2) Control the paint flow
3) Prevent precipitates and turbidity in the paint film

Table 9. Evaporation of glycol ethers (percentage evaporated as a function of time at 23 °C)

Solvent	Time, h										Evaporation
	10	15	20	25	50	100	150	200	300	400	number (diethyl ether = 1)
Ethyl glycol	40	58	77	93							43
Butyl glycol					30	60	92				119
Ethyl diglycol					0	3	11	18	34	51	1200
Butyl diglycol							0	3	6	9	> 1200

4) Prevent film shrinkage

A paint formulation therefore always contains several solvents: low boilers, medium boilers, and a small proportion of high boilers. The vapor pressure of the individual solvents in the mixture is described by Raoult's law:

$$p_i = f_i \cdot x_i \cdot p_i^{\circ}$$

where p_i is the partial pressure of component i, x_i the mole fraction of component i, and p_i° the vapor pressure of the pure component. The activity coefficient f_i, which may be larger or smaller than 1, takes account of the real behavior of the solvent (i.e., deviations from the ideal state).

3.2. Hygroscopicity

Some solvents, particularly those containing hydroxyl groups (e.g., alcohols and glycol ethers) are hygroscopic: they absorb moisture from the atmosphere until an equilibrium is reached. The equilibrium water content of the solvent depends on the relative atmospheric humidity and temperature. The hygroscopic properties of glycol ethers have been investigated in detail (Table 10).

3.3. Density and Refractive Index

In addition to the boiling curve, the density and refractive index are used to assess and, with some restrictions, to determine solvent purity.

The *density* of a solvent is generally measured at 20 °C and referred to the density of water at 4 °C (relative density d_4^{20}). The densities of most organic solvents decrease with increasing temperature (Fig. 6) and are less than that of water, but halogenated hydrocarbons are denser than water. The relative densities (d_4^{20}) of homologous esters and glycol ethers decrease with increasing molecular mass, whereas those of ketones and alcohols increase:

Esters		*Alcohols*	
Methyl acetate	0.934	Methanol	0.791
Ethyl acetate	0.901	Ethanol	0.789
Propyl acetate	0.886	Propanol	0.804
Butyl acetate	0.881	Butanol	0.810
Amyl acetate	0.876	Amyl alcohol	0.815
Glycol Ethers		*Ketones*	
Methyl glycol	0.966	Acetone	0.792
Ethyl glycol	0.931	Methyl ethyl ketone	0.805
Propyl glycol	0.911	Methyl propyl ketone	0.807
Butyl glycol	0.902	Amyl methyl ketone	0.816

Figure 6. Temperature dependence of solvent densities
a) Dichloromethane; b) Butyl diglycol; c) Butyl glycol; d) Ethyl acetate; e) Butyl acetate; f) Butanol

The *refractive index* n_D is measured in a refractometer with a sodium vapor lamp (Na-D lines, 589.0 and 589.6 nm). The value of the refractive index [46], [47], [81] is largely de-

termined by the hydrocarbon skeleton of the substance in question. Aliphatic esters, ketones, and alcohols have refractive indices between 1.32 and 1.42. In homologous series the refractive index increases with increasing length of the carbon chain, and decreases with increasing branching. Cycloaliphatic and aromatic structures increase the refractive index (n_D^{20}), as does the incidence of functional groups:

Methyl acetate	1.3610	Cyclohexanol	1.4667
Ethyl acetate	1.3718	Benzyl alcohol	1.5390
Propyl acetate	1.3844	Methylbenzyl alcohol	1.5270
Isopropyl acetate	1.3773	Toluene	1.4955
Butyl acetate	1.3961	*p*-Xylene	1.4956
Isobutyl acetate	1.3898	Tetrahydronaphthalene	1.5443
Methanol	1.3290	Ethyl glycol	1.4075
Ethanol	1.3619	Ethylene glycol	1.4310
Propanol	1.3859	Diethylene glycol	1.4460
Isopropyl alcohol	1.3772	Dichloromethane	1.4234
Butanol	1.3994		
Isobutanol	1.3960		

The refractive index decreases with increasing temperature (Fig. 7).

Table 10. Hygroscopicity of glycol ethers expressed as equilibrium water content (wt %) of solutions in contact with air of different relative atmospheric humidities (101.3 kPa, 25 °C)

	Relative atmospheric humidity, %						
Solvent	40	50	60	70	80	90	100
Ethyl glycol	5	8	12	20	31	48	77
Butyl glycol	4	7	11	18	27	37	49
Ethyl diglycol	6	8	14	20	30	40	53
Butyl diglycol	3	6	9.5	17	25	37	49
Ethylene glycol	18	26	37	47	60	74	89

3.4. Viscosity and Surface Tension

The *viscosities* of homologous series of solvents (Table 23) increase with increasing molecular mass. Solvents bearing hydroxyl groups have higher viscosities due to the formation of hydrogen bonds. The solvent viscosity greatly influences solution viscosity (see Section 7.1). The viscosity decreases with increasing temperature (Fig. 8).

Figure 8. Temperature dependence of solvent viscosities
a) Methylbenzyl alcohol; b) Butyl diglycol; c) Butyl glycol; d) Butanol; e) Isophorone; f) Ethyl acetate

The surface tension of paint solvents is of importance for the rate of evaporation, for the formation of the coating surface, and as for the wetting of the substrates, extenders, and pigments.

The *surface tension* of a solvent is related to the cohesive energy density and internal pres-

Table 11. Thermal and electrical properties of solvents

Solvent	Thermal conductivity (20 °C), $Wm^{-1}\,K^{-1}$	Cubic expansion coefficient, $K^{-1}\times10^{-3}$	Dielectric constant (20 °C)	Electrical conductivity, S/cm
Cyclohexane			2.01	1.9×10^{-14}
Xylene		0.9	2.3	10^{-5}
Dichloromethane	0.159	1.3	7.0	4.3×10^{-11}
Tetrachloroethylene	0.16	1.08	2.5	5.6×10^{-4}
Ethanol	0.171	1.1	22.4	1.4×10^{-9}
Butanol		0.79	18.2	9.1×10^{-9}
Butyl acetate	0.14 (30 °C)	1.21	4.5	5.2×10^{-11}
Ethyl glycol acetate	0.143 (25 °C)	1.12	9.0	1.2×10^{-8}
Methyl ethyl ketone		1.27	18.4	3.6×10^{-9}
Methyl isobutyl ketone		1.15	13.1	3×10^{-9}
Butyl glycol	0.162 (30 °C)	0.92	9.2	4.3×10^{-7}
Butyl diglycol	0.139	0.85	11.0	2×10^{-8}
Diethyl ether	0.132		4.34	4×10^{-13}
Tetrahydrofuran	0.14	1.29	7.6	0.5×10^{-8}

sure of the liquid. A relationship can be derived between the solubility parameter δ (which is defined as the square root of the cohesive energy density) and the surface tension γ_o [82]. For polar and nonpolar solvents the following relationship applies:

$$\delta = 2.1K\left(\frac{\gamma_o}{V^{1/3}}\right)^a$$

where V is the molar volume and K and a are constants ($K \approx 3.6$, $a \approx 0.56$). This empirical relationship is extremely satisfactory (Table 18).

3.5. Vapor Density

The vapor density is the mass of solvent vapor per cubic meter of air (kg/m^3) that is in equilibrium with the liquid at 101.3 kPa. The vapor density thus corresponds to the solvent content in the atmosphere at saturation and is temperature dependent. The relative vapor density of solvents d_S is referred to the density of air and can be calculated according to:

$$d_S = \frac{M_S}{M_{air}}$$

where M_S is the molecular mass of the solvent, M_{air} is the mean molecular mass of air (= 28.95 g/mol).

In the ideal case, the relative vapor density is temperature independent. Relative vapor densities of some solvents follow:

Toluene	3.18
Xylene	3.67
Ethanol	1.59
Butanol	2.56
Ethyl acetate	3.04
Butyl acetate	4.01
Methyl ethyl ketone	2.49
Ethyl glycol	3.11
Dichloromethane	2.93

3.6. Thermal and Electrical Data

The dielectric constant and thermal conductivity decrease with increasing temperature, whereas the specific heat increases. The thermal conductivities, cubic expansion coefficients, dielectric constants, and electrical conductivities of various solvents are listed in Table 11. Critical data of solvents and the technical use of supercritical liquids are described in [83].

3.7. Flash Point, Ignition Temperature, and Ignition Limits

The temperature at which a solvent vapor–air mixture is ignited by a naked flame is termed the *flash point* of the solvent. The flash points of solvents increase with decreasing vapor pressure and thus with increasing molecular mass and boiling point. They form the basis for their classification according to flammability (danger classes, transport regulations, Section 5.3). Flash points of some solvents follow:

Methyl acetate	−13 °C	Acetone	−19 °C
Ethyl acetate	−12 °C	Methyl ethyl ketone	−14 °C
Propyl acetate	12 °C	Methyl propyl ketone	22 °C
Butyl acetate	22 °C	Methyl butyl ketone	23 °C
Amyl acetate	34 °C	Methyl isobutyl ketone	15 °C
Ethyl glycol acetate	52 °C	Methyl amyl ketone	49 °C

The absolute flash point T_F of a solvent is related to its absolute boiling point T_S according to the following empirical equation [84]:

$$T_F = 0.736 T_S$$

Flash points calculated according to this equation are sufficiently accurate (deviation ± 5 °C) in the case of hydrocarbons, ketones, and esters. The equation is, however, unsatisfactory in the case of solvents containing hydroxyl groups such as alcohols, glycols, and glycol ethers (deviation up to ± 30 K).

A relationship between the flash point and vapor pressure p has also been derived:

$$T_F = a \log p + b$$

where a is a general constant and b is a substance-specific constant.

For safety reasons numerous attempts have been made to raise the flash point of solvent mixtures [85]. Azeotropes having a lower flash point than those of the pure components can be formed on mixing solvents; use of solvent mixtures to raise the flash point is therefore extremely problematic. The flash point of toluene can, for example, be significantly raised above 21 °C by adding chlorinated hydrocarbons [86], [87]. However, the flash point is first lowered instead of raised if dichloromethane is added. Non-flammability is achieved only above a minimum addition of dichloromethane.

The flash point of a solvent mixture is not identical to that of its most flammable component. When solvents with widely differing hydrogen bond parameters are mixed (e.g., alcohol–hydrocarbon), the flash point is significantly reduced. On the other hand, the flash point of a mixture of chemically related solvents lies between those of the individual components [88–90]. Methods have been developed for calculating the flash point of solvent mixtures and solutions, activity coefficients are used to account for nonideal behavior [91].

Flash point determinations on mixtures of xylene with polar solvents led to the following conclusions [92], [93]:

1) Small quantities of solvents containing carbonyl groups (esters, ketones) reduce the flash point, larger amounts increase it again
2) The flash point is raised by adding 4 wt % of butanol or 8 wt % of isobutanol
3) Small additions of water do not significantly influence the flash point
4) Addition of ethanol sharply reduces the flash point; ethyl glycol acts in the same way, although to a lesser extent

In order to evaluate the flammability of water-thinnable paints, a knowledge of the increase in the flash points of water-miscible solvents after addition of water is important. These mixtures no longer ignite above a specific ratio of water to organic solvent (following results at 25 °C):

1) Isopropyl alcohol – water mixtures are still combustible in a 40/60 ratio, but not combustible in a 30/70 ratio
2) Propanol – water mixtures are still combustible in a 70/30 ratio, but not combustible in a 60/40 ratio

Flash points of solvent – water mixtures are given in Table 12.

Table 12. Flash points (°C) of solvent – water mixtures

Flash point	Solvent to water ratio			
	1 : 0	9 : 1	1 : 1	1 : 9
Ethanol	10	19	25	51
Isopropyl alcohol	12	19	24	41
Ethyl glycol	46	57	72	
Methyl ethyl ketone	−9	−7	−6	5–9
Butyl glycol	60	> 65		

A solvent vapor is ignited not only by a naked flame, but can spontaneously ignite when the solvent vapor – air mixture has reached the *ignition temperature*. A distinction is made between the gas ignition temperature and drop ignition temperature, depending on whether the measurement is made by determining the gas temperature or by allowing the solvent to drop onto a hot surface of known temperature [94]. The value of the ignition temperature is used

to group solvents into temperature classes (ignition groups). For example, VDE Regulation 0171 specifies five groups:

T 5	100 – 135 °C
T 4	135 – 200 °C
T 3	200 – 300 °C
T 2	300 – 450 °C
T 1	> 450 °C

An explosion is a self-propagating, particulary rapid combustion process that is initiated by an ignition and proceeds without external energy or air. The explosion of a solvent vapor – air mixture is possible only within a specific solvent concentration range, defined by the lower and upper ignition limits (explosion limits) which are specified in volume percent or grams per cubic meter of solvent in the solvent vapor – air mixture at 101.3 kPa.

The temperatures at which the concentrations of solvent vapor in equilibrium with the liquid reach the lower or upper ignition limit are obtained from the vapor pressure curves of the solvents; these temperatures are termed the lower and upper explosion points. The lower explosion points roughly correspond to the flash points of the solvents [95–99].

3.8. Heats of Combustion and Calorific Values

The combustion of organic solvents releases energy since organic compounds generally have higher energy contents than their combustion products. The combustion energy, also termed heat of combustion or gross calorific value, is given in kilojoules per mole or kilojoules per kilogram.

The gross calorific value refers to liquid water of reaction, whereas the net calorific value refers to the water vapor that is formed. The two calorific values thus differ by the contribution of the enthalpy of vaporization of the water formed during combustion.

The heats of combustion of alcohols, esters, and glycol ethers are very much smaller than those of hydrocarbons (Table 19). Electronegative substituents generally reduce the combustion energy in the order $NH_2 > Cl > OH > SH$. The larger the number of substituents in the molecule, the lower the combustion energy. A knowledge of the calorific values of solvents is of great industrial importance because they decisively influence the size and cost of combustion and solvent incineration plants [100], [101].

3.9. Chemical Properties

A high chemical resistance is an important prerequiste for the use of a liquid as a solvent. Aliphatic and aromatic hydrocarbons are chemically inert and thus satisfy this requirement extremely well.

Alcohols too are chemically very resistant but they dissolve alkali metals, alkaline-earth metals, and aluminum to form salts. Under certain conditions alcohols can be converted into carboxylic acids by powerful oxidizing agents. They are, however, stable toward atmospheric oxygen. On account of their reaction with isocyanates to form urethanes, solvents containing hydroxyl groups (e.g., alcohols, glycols, and glycol ethers) must not be used as solvents for polyurethane paints [102], [103].

On prolonged storage most ethers and glycol ethers form peroxides with atmospheric oxygen. In the case of glycol ethers this leads to acid formation due to oxidation which can be prevented by adding stabilizers.

Esters and ketones are chemically very resistant under normal conditions, especially in the paint industry. However, it must be remembered that esters can be hydrolyzed to form alcohols and acids. For ethyl acetate the equilibrium constant K at 40 °C is 2.51, and at 100 °C is 2.56.

$$K = \frac{[\text{Ethyl acetate}] \cdot [H_2O]}{[\text{Acetic acid}] \cdot [\text{Ethanol}]}$$

In a neutral medium hydrolysis begins extremely slowly, but is autocatalyzed by the acetic acid product. The hydrolysis kinetics proceed according to:

$$\frac{dx}{dt} = k\,(a - x)\,\sqrt{x}$$

where k is the reaction constant, a is the initial concentration of the ester, and x is the acid concentration. For example, when 44 g of ethyl acetate is dissolved in 1 L of water at 20 °C, about 15 g is hydrolyzed after 130 days. Under acid or base catalysis the reaction rate is 10^5-fold or 10^8-fold higher, respectively.

The hydrolysis rate of the ester depends on its chemical structure. The rates of alkaline hydrolysis of isobutyl and butyl acetates are greater at room temperature than that of *sec*-butyl acetate; *tert*-butyl acetate is even more stable under alkaline conditions (iso $\approx n > sec >> tert$). The rates of acid hydrolysis of the butyl acetates decrease in the order iso $> n > tert > sec$.

Chlorinated hydrocarbons can release hydrogen chloride in the presence of bases or metals, but stabilizers added by the manufacturer ensure high chemical resistance. Highly stable solvents are nitro compounds, dimethylformamide, and dimethyl sulfoxide, which, however, often become dark on prolonged storage in air.

Before using a solvent it is advisable to become acquainted with the chemical properties so that interactions can be anticipated and explained. A comprehensive literature exists on solvent effects in chemical reactions [3], [103], [104].

4. Toxicology and Occupational Health

4.1. Toxicology

Acute and Chronic Toxicity. Solvents act with different intensities on human, animal, and plant organisms. Their effects depend on the amount of solvent and the exposure time. Under short-term exposure to high solvent doses acute damage may occur, whereas the absorption of smaller amounts over a longer period leads to chronic damage and sensitization. The chronic effects are more dangerous since they are accompanied by an acquired tolerance, with the result that they are often not detected early enough.

In order to evaluate the solvent toxicities, their LD_{50} values (oral administration to rats) are listed in Table 24. Since most cases of solvent poisoning are caused by inhalation of solvent vapors, the LC_{50} values are also given.

Inhaled solvent vapors pass via the lungs and blood circulation into the body, where they accumulate in tissues with high lipid content (e.g., nerves, brain, bone marrow, adipose tissue, liver, and kidneys) [105]. The cells can either be damaged by the solvents or by their decomposition products. Solvents can also pass into the body via cutaneous or, more rarely, gastrointestinal absorption [106], [107].

Symptoms of acute solvent poisoning include dizziness, drowsiness, headache, loss of consciousness, and narcotic effects which are attributed to disturbances of the central nervous system. Chronic poisoning is initially undetectable, but subsequently causes damage to organs that are specific for each solvent [108–111].

Solvents have two effects on the skin: (1) they dissolve the natural fatty layer, the skin therefore cracks and microorganisms and dirt particles can penetrate more easily and cause infection; (2) solvents can act directly to cause inflammation or blistering.

The following solvents are absorbed very readily through the skin and pass into the body: aniline, benzene, butyl glycol, butyl glycol acetate, dimethylacetamide, dimethylformamide, dioxane, ethyl glycol, ethyl glycol acetate, ethylbenzene, isopropyl glycol, carbon disulfide, methanol, methyl glycol, methyl glycol acetate, methylcyclohexane-2-one, 4-methyl-2-pentanol, nitrobenzene, nitrotoluene, isopropylbenzene, 1,1,2,2-tetrachloroethane, and tetrachloromethane.

After sensitization of the skin or respiratory system, allergic reactions may occur but vary widely, depending on the individual susceptibility. Observance of the MAK or TLV values is no guarantee against the occurrence of such reactions [112]. Turpentine oil is the only solvent that has attracted attention because of its ability to trigger hypersensitivity reactions of an allergic nature.

Carcinogenicity. In Germany, carcinogenic solvents are classified as "III Carcinogenic Substances" in the Technische Regeln für Gefahrstoffe TRG 900 (Technical Regulations Covering Dangerous Substances).

The solvents are subdivided into Section A (substances shown to be unequivocally carcinogenic) and Section B (substances justifiably suspected of being potential carcinogens). Section A is divided into Subsection A 1 (substances that according to experience may cause malignant tumors in humans) and Subsection A 2 (substances which have clearly been shown to be carcinogenic in animal experiments).

Section A 1 includes benzene; Section A 2 includes 1,2-dichloroethane, hexamethylphosphoric triamide, and 2-nitropropane; Section B includes aniline, chloroethane, dichloromethane, 1,4-dioxane, 1,1,2,2-tetrachloroethane, tetrachloroethylene, tetrachloromethane, 1,1,2-trichloroethane, trichloroethylene, and trichloromethane.

No maximum allowable concentrations (MAK values) are specified for substances in Section A since no concentrations can be regarded as harmless. If the use of these substances is technically necessary, special monitoring and protective measures must be adopted (see Section 4.2). Particular care should also be exercised when handling substances in Section B.

Teratogenicity and Embryotoxicity. In Germany, substances that are potentially teratogenic or embryotoxic are classified in four groups (see Table 24):

Group A. Teratogenic and embryotoxic effects have been demonstrated.

Group B. Teratogenic and embryotoxic effects are likely. Examples include dimethylformamide, ethyl glycol, ethyl glycol acetate, methyl glycol, methyl glycol acetate, 2-methoxy-1-propanol, 2-methoxy-1-propyl acetate, carbon disulfide, toluene, and trichloromethane. TRGS 609 give details of limitations on use, substitutes, and alternative processes for methyl and ethyl glycols and their acetates.

Group C. There is no risk of teratogenic and embryotoxic effects provided the MAK values are observed. Examples include butyl glycol, butyl glycol acetate, cyclohexanone, dimethylacetamide, hexane, isopropyl glycol, 1-methoxy-2-propyl acetate, styrene, tetrachloroethylene, tetrahydrofuran, 1,1,1-trichloroethane, and trichloroethylene.

Group D. An evaluation is still not possible. Examples include aniline, methyl ethyl ketone, dichloromethane, diethyl ether, ethanol, ethyl formate, methyl formate, methanol, methyl acetate, *N*-methylpyrrolidone, nitrobenzene, isopropyl alcohol, tetrachloromethane, and xylene.

Mutagenicity denotes damage to male and female gametes that can lead to genetic changes in subsequent generations. Such damage may include gene mutations and changes in the structure and number of chromosomes. Mutagenic substances are subdivided into:

Group 1. Substances for which a mutagenic effect has been detected in humans

Group 2. Substances for which a mutagenic effect has been detected in suckling females in animal experiments

Group 3. Substances for which damage to the genetic material of the gametes has been detected in humans or in animal experiments

4.2. Occupational Health

Personal Safety Precautions. When working with solvents or solvent-containing preparations, contact with the skin and mucous membranes should be avoided. Protective goggles and gloves should be worn and the skin protected with skin cream. Wet articles of clothing should be changed immediately. Inhalation of solvent vapors should be avoided. The guidelines and codes of conduct published by the industrial and trade unions should be observed.

Odor Threshold. Most solvents have a characteristic odor. Human perceptibility and sensitivity to solvent vapors depends on habituation, which varies markedly from one person to another. Odors that are regarded as pleasant in small concentrations may be considered intolerable at high doses and under constant exposure. Other vapors that are initially considered objectionable may subsequently be regarded as tolerable [113]. It is therefore impossible to give objective rules for determining when an odor becomes objectionable. Odor intensity is subdivided into four levels:

1) Imperceptible
2) Weakly perceptible
3) Moderately perceptible
4) Highly perceptible

The odor threshold is the vapor concentration in a cubic meter of air (mg/m^3) that is just still perceptible; it lies between levels 1 and 2 [114]. The odor threshold values of some solvents are given in Table 24.

When handling solvents, the odor should be regarded as a preliminary warning sign. Relatively high solvent concentrations may irritate the mucous membranes. It must be pointed out, however, that some mildly smelling solvents may present more of a health hazard than other, strongly perceptible products.

MAK Values. The toxicity of solvent vapors at the workplace has been investigated in animal experiments and by observing and monitoring humans. The MAK value (Maximale Arbeitsplatzkonzentration) is the maximum permissible concentration of a substance in the atmosphere at the workplace that is generally not injurious to the health of the employees and is not regarded as intolerable by the latter, even after repeated and long-term exposure (generally 8-h exposure per day). As a rule, MAK values are average values over a period of a day or a working shift. Since the actual concentration of the working substances in the inhaled air frequently fluctuates, exposure peaks are specified for individual categories according to short-term value, short-term duration, and frequency per working shift:

Category I. Locally irritant substances: $2 \cdot \mathrm{MAK}$

Category II. Substances that act after absorption with an onset of action ≤ 2 h: $2-5 \cdot \mathrm{MAK}$

Category III. Substances that act after absorption with an onset of action > 2 h: $10 \cdot \mathrm{MAK}$

Category IV. Very weak potential action: $2 \cdot \mathrm{MAK}$

Category V. Substances with an intense odor: $2 \cdot \mathrm{MAK}$

Ventilation equipment at the workplace should be designed and dimensioned so that the MAK values of the individual solvents are not exceeded.

No MAK values can be specified for a number of carcinogenic and mutagenic substances. Some of these substances are, however, unavoidable and exposure to them cannot be excluded. Technische Richtkonzentrationen TRK (lowest technically feasible levels) have been set for these substances to minimize the risk of a health hazard at the workplace. The TRK value for benzene and 2-nitropropane is 5 ppm (TRGS 102).

Since the MAK values apply only to pure substances in the workplace atmosphere, an evaluation index I_{MAK} has been defined in TRGS 403 according to the follwing formula for mixtures of solvent that occur in the majority of cases at the workplace.

$$I_{\mathrm{MAK}} = \sum_{i=1}^{n} \frac{C_i}{\mathrm{MAK}_i}$$

TLV Values. In the United States, the equivalent of the MAK value is the threshold limit value (TLV). The TLV value is that concentration of a substance in the air to which virtually all workers can be exposed daily without any harmful effects. This value is subdivided into TLV-TWA (time-weighted average concentration), TLV-STEL (short-term exposure limit), and TLV-C (ceiling limit). TLV-TWA applies to a normal 8-h working day or a 40-h week, TLV-STEL is the maximum concentration for an exposure time of 15 min, and TLV-C is the concentration that should at no time be exceeded. The TLV values published by the ACGIH are recommendations, whereas the PEL values (permissible exposure limit) specified by OSHA (Occupational Safety and Health Administration) are enforced by law. The safety limits are recommended to OSHA by NIOSH (National Institute of Occupational Safety and Health). Solvent TLV values for the USA and several European countries are listed in Table 13.

Other Limiting Values. In Scandinavia, solvent-containing products are identified with a YL value (yrkeshygieniskt luft behov = industrial hygiene air requirement). This value states how many cubic meters of air are required to dilute the amount of solvent contained in 1 L of product to such an extent that the concentration is below the TLV value. The YL value can be calculated for each solvent by multiplying the YL factor by the percentage content of the respective solvent in the liquid. A PWA factor (**p**aint technology **w**ork hygiene **a**ir requirement) is allocated to the solvents on the basis of their YL value. The PWA number is in turn used as a basis for calculating the potential health hazard of a paint, and serves to specify the protective measures and working clothes that are to be used when applying paints (Swedish Work Safety Office Publication No. 463 and State Factory Inspectorate Publication No. 464, of 3rd August 1982).

A harmfulness factor has been proposed to quantify the harmfulness of solvents [115–117]:

$$\text{Harmfulness factor} = \frac{10\,000}{\mathrm{TLV} \cdot \text{relative evaporation number}}$$

The harmfulness factor takes into account not only the actual health-damaging action of the

Table 13. Threshold limit values of some countries (1991, ppm)

Solvent	Denmark	France	Germany	Italy	The Netherlands	UK	Sweden	USA (TLV-PEL)
Cyclohexane	300	300	300	300	300	300	50	300
Diethyl ether	400	400	400	400	400	400	100	400
Tetrahydrofuran	200	200	200	200	200	200	20	200
Ethyl acetate	300	400	400	400	400	400	200	400
Pentyl acetate	100	100	100	100	100	100	50	100
Methyl ethyl ketone	100	200	200	200	200	200	100	200
Methyl isobutyl ketone	50	50	100	50	50	50	20	100

solvent, but also the time for a health-damaging concentration to accumulate if the product leaks or is split.

5. Environmental and Legal Aspects

5.1. Environmental Protection

Being volatile substances, all solvents inevitably evaporate and pass as harmful substances into the atmosphere [118–121]. They may also affect waterways, lakes, rivers, ground water, and soil. Anthropogenic organic emissions total ca. 10^7 t/a in the EC; of this, 34 % stems from the use of solvents and 53 % from the transport and traffic sector (Corinair Study 1985, Inventaire européen des émissions).

United States. The first environmental protection measures were implemented in particularly threatened, highly industrialized regions with a high density of motorized traffic. In the Los Angeles district of California, exposure of certain organic solvent vapors to solar radiation can lead to the formation of smog [122–124]. In the United States, Public Law 84 – 159 of 1955 passed by the Federal Departments of Health, Education, and Welfare was the basis for local clean air directives. In Rule 66 and Rule 442 (district of Los Angeles), aromatic hydrocarbons (xylene, tetrahydronaphthalene, toluene, and ethylbenzene) and branched- chain ketones (e.g., isophorone, mesityl oxide, methyl isobutyl ketone, methyl isopropyl ketone, and diacetone alcohol) are classified as photochemically reactive, smog-producing solvents. Aliphatic hydrocarbons and nitro compounds are considered to be photochemically nonreactive. Efforts are being made to reduce the solvent content of paints and use photochemically nonreactive solvents or water. Clean air measures in the United States have become more stringent as a result of further laws passed by the EPA, including the Air Pollution Control Act 1962, Clean Air Act 1963, Air Quality Act 1967, National Environmental Policy Act 1969/1970/1975, Clean Air Act 1970 and 1990 (CAA) [125–128]. The implementation of these acts in the federal states is governed by executive provisions (e.g., New York State Rule 187). Since 1989, emissions have been regulated and reduced in stages by restricting the use of solvent- containing coatings in certain areas of application; for example, specific directives apply to the use of paints in automobile repair workshops, air-drying industrial paints, wood paints, swimming-pool paints, and marine paints. Special regulations apply to new industrial sites (e.g., new automobile factories).

Europe.

Germany. An anti-emission law (Immissionsschutzgesetz) was passed by the state of North Rhine – Westphalia, Germany, in 1968. The purpose of this law and various executive directives was to improve living conditions and the atmosphere in the Ruhr district. In 1974, the individual laws of German states (Länder) were unified in the form of the Bundesimmissionsschutzgesetz (Federal Anti-Emission Law) and the Technische Anleitung zur Reinhaltung der Luft, TA Luft (Clean Air Regulations) of 27 Feb., 1986, which has since become known throughout Europe [129–132].

United Kingdom. Environmental Protection Act with Air Pollution Control APC (1990) [133].

Italy. Law 203 of the Ministry for the Environment (1988) including guidelines (1990) that restrict solvent emissions in certain application sectors (e.g., the automobile industry).

The Netherlands. Guideline KWS 2000 to reduce aromatic hydrocarbon emissions by ca. 50 % of the 1981 level by the year 2000.

France. Guideline to reduce emissions of volatile organic compounds (VOC) by ca. 30 % by the year 2000.

Austria. Anti-emission law to reduce the use of solvents, particularly aromatic hydrocarbons [134].

European legislation will be standardized by EC directives that are currently being drafted. The draft guideline on Integrated Pollution Prevention and Control (IPPC) restricts and controls emissions produced during the erection of new technical plants and the expansion of existing plants. The draft of a Directive to Limit Emissions of Organic Solvents entails a "solvent management plan." Its aim is the stepwise replacement of ecologically and industrial-hygienically "critical" by less critical solvents or by solvents with a low ozone-formation potential (POCP = photochemical ozone creation potential) [135]. In the final stage the use of solvents will be restricted and, where technically possible, solvent-containing coating systems will be replaced by environmentally friendly alternatives such as waterborne paints [136–140]. The POCP values of solvents are listed below:

Perchloroethylene	1	Toluene	55
Dichloromethane	1	Butanol	55
Methyl acetate	3	*sec*-Butanol	55
Trichloroethylene	7	Ethyl glycol acetate	60
Methanol	10	Butyl glycol acetate	60
Isopropyl alcohol	15	Diethyl ether	60
Diacetone alcohol	20	Ethoxypropyl acetate	65
Acetone	20	Tetrahydrofuran	70
Ethyl acetate	20	Ethyl glycol	75
Ethanol	25	Butyl glycol	75
Cyclohexane	25	Isophorone	80
Methoxypropyl acetate	30	Methoxypropanol	80
Isobutyl acetate	35	Diisobutyl ketone	80
Methylcyclohexane	35	Ethoxypropanol	85
Isobutanol	40	*p*-Xylene	90
Methyl ethyl ketone	40	1,3-Diethylbenzene	95
Hexane	40	Tetramethylbenzene	110
Butyl acetate	45	Trimethylbenzene	120
Propanol	45	Diethylmethylbenzene	120

In the TA Luft organic substances (including solvents) are subdivided into three classes. The following concentration limits must not be exceeded in emissions:

Class I.	Substances with a mass flow ≥ 0.1 kg/h: 20 mg/m^3
Class II.	*Substances with a mass flow ≥ 2 kg/h: 100 mg/m^3*
Class III.	Substances with a mass flow ≥ 3 kg/h: 150 mg/m^3

If organic compounds of several classes are present, the mass concentration in the waste gas must not exceed 150 mg/m^3 with a total mass flow ≥ 3 kg/h.

The classes contain the following solvents:

Class I. Aniline, 1,2-dichloroethane, 1,4-dioxane, nitrobenzene, phenol, 1,1,2,2-tetrachloroethane, tetrachloromethane, trichloromethane, furfural.

Class II. Butyl glycol, chlorobenzene, cyclohexanone, dimethylformamide, diisobutyl ketone, ethyl glycol, ethylbenzene, furfuryl alcohol, isopropylbenzene, carbon disulfide, methyl glycol, methyl acetate, methyl cyclohexanones, methyl formate, styrene, tetrachloroethylene, tetrahydrofuran, toluene, 1,1,1-trichloroethane, trimethylbenzenes, xylenes.

Class III. Acetone, alkyl alcohols, methyl ethyl ketone, butyl acetate, dibutyl ether, dichloromethane, diethyl ether, diisopropyl ether, dimethyl ether, ethyl acetate, ethylene glycol, diacetone alcohol, methyl isobutyl ketone, *N*-methylpyrrolidone, paraffin hydrocarbons (except methane), pinenes.

Organic substances not listed above should be allocated to the classes containing substances that they most closely resemble as regards their environmental effects. The toxicity, degradability, degradation products, and their odor intensity should be borne in mind.

The degradation of solvents by microorganisms in water, wastewater, effluent, and in clarification plants differs. In Germany solvents have been therefore classified as non, weakly, slightly, moderately, or strongly water-polluting [141]. In general, the discharge of solvents into water and waterways should be avoided to prevent contamination of rivers and ground water. The majority of solvents in wastewater and treatment plants are degradable if handled properly [142]. Detailed investigations have been carried out to assess the toxicity of solvents toward fish, which have been embodied OECD test standards [143], [144].

International measures have been adopted to restrict the use of products (mainly chlorofluorocarbons, CFCs) responsible for the decomposition of the ozone layer in the stratosphere. EC regulation No. 584/91 of March 4, 1991 regulates the import, export, production, and use of chlorinated hydrocarbons, brominated compounds, tetrachloromethane, and 1,1,1-trichloroethane. The production of these solvents is to be phased out in stages by the year 2000 [145].

5.2. Laws Concerning Dangerous Substances

In order to harmonize the legal and executive directives of the member states, the Council of the European Community has issued directives on the "Classification, Packaging and Labelling of Dangerous Substances" (67/548/EC, Basic Directive, Official Journal of the European Communities No. 196, p. 1, ff, 1967) together with numerous adaptations to take account of technical progress. The Council Directive of June 7, 1988 on the approximation of the laws of the member states relating to classification, packaging and labelling of dangerous preparations" applies to the identification of preparations (mixtures of substances) (88/379/EC, Preparations Directive, Official Journal of the European Communities No. L 187, pp. 14 – 30, 1988). It replaces the Solvent Directive and the Paint Directive (73/173/EC and 77/728/EC). Dangerous substances and solvents are listed and classified as harmful, toxic, irritant, corrosive, etc. Danger symbols are specified for each substance and information is given concerning special risks (R phrases) and safety recommendations (S phrases). The list of substances is constantly being revised and expanded [146], [147].

The EC directives and the wording of the dangerous substances directive are being continually updated. In order to assess the potential danger of a solvent the current wording of the directive should therefore be consulted.

On the basis of the EC directives the Verordnung über gefährliche Stoffe, GefStoffV (Directive on Dangerous Substances) of August 26, 1986 was issued in Germany (Bundesgesetzblatt I, p. 1470) in the wording of June 5, 1991 (Bundesgesetzblatt I, p. 1 – 1218).

Classification criteria such as danger of explosion, fire promoting, highly flammable, readily flammable, flammable, highly toxic, toxic, harmful, corrosive, irritant, carcinogenic, teratogenic, and mutagenic are defined in this directive. Instructions are given concerning the packaging and labelling of substances and preparations. The directive also contains instructions on the handling of dangerous substances (protective measures, prohibition of use, official regulations) and on health monitoring (preventive medicine, health data file). Individual paragraphs deal with legislation for the protection of young workers, pregnant women, and nursing mothers, and regulations governing trades, businesses, and working hours. Appendices I – VI include regulations concerning classification and identification; directives covering carcinogenic substances, aliphatic chlorinated hydrocarbons, lead and antifouling paints; provisions on working in rooms and containers; prescribed medical examinations; and a list of substances together with legally binding information on their labelling.

The German Chemikaliengesetz, ChemG (Chemicals Law) was passed on September 18, 1980 (Bundesgesetzblatt I, p. 1718) and deals with protection against dangerous substances. Newly developed substances must be registered with the authorities and subjected to toxicological testing. Similar regulations exist in other countries. Toxicological and ecotoxic data are also being compiled for chemicals that already exist and are listed in the European Inventory of Existing Chemical Substances (EINECS).

The Toxic Substances Control Act (TSCA) in the United States has been effective since 1977 and is similar to the German Chemicals Law. The TSCA specifies that chemicals must be assessed as regards their risks and registered before production and use.

The Technische Regeln für Gefahrstoffe, TRGS (Technical Regulations for Dangerous Substances) specify safety, industrial medicine, hygiene, and ergonomic requirements for introducing and handling dangerous substances.

The following regulations are of particular importance for solvents: recommended concentration (TRK) for dangerous substances (TRGS 102, limits e.g., benzene, 2-nitropropane); TRGS 150 covering direct skin contact with dangerous substances; TRGS 402 for the

determination and evaluation of the concentrations of dangerous substances in the atmosphere of working areas; TRGS 403 for the measurement of mixtures of substances in the workplace atmosphere; and regulations covering restrictions on use, alternative substances, alternative processes (e.g., TRgA 502 for carbon tetrachloride, tetrachloroethane, pentachloroethane; TRGS 609 for methyl and ethyl glycols and their acetates), the MAK values and biological workplace tolerance values (TRGS 403, 900).

5.3. Fire Hazard

Most organic solvents are readily volatile and combustible, and their vapors form explosive mixtures with air. The fire hazard of solvents depends on their volatility and flash point (Section 3.7).

In Germany, the Verordnung über brennbare Flüssigkeiten, VbF (Directive on Combustible Liquids) of June 5, 1970 divides solvents into danger classes:

Class A I:	water-insoluble, flash point $< 21\,^{\circ}C$
Class A II:	water-insoluble, flash point $21 - 55\,^{\circ}C$
Class A III:	water-insoluble, flash point $55 - 100\,^{\circ}C$
Class B:	flash point $< 21\,^{\circ}C$ in the case of liquids that are miscible in all proportions with water at $15\,^{\circ}C$

In the United States substances are subdivided according to their flash points:

1) Flammable	
Class I:	flash point $< 100\,^{\circ}F$ ($38\,^{\circ}C$)
Class IA:	flash point $< 73\,^{\circ}F$ ($22.8\,^{\circ}C$), $bp < 100\,^{\circ}F$ ($38\,^{\circ}C$)
Class IB:	flash point $< 73\,^{\circ}C$ ($22.8\,^{\circ}C$), $bp > 100\,^{\circ}F$ ($38\,^{\circ}C$)
Class IC:	flash point $> 73\,^{\circ}F$, $bp < 100^{\circ}F$
2) Combustible, flash point $> 100\,^{\circ}F$	
Class II:	flash point $> 100\,^{\circ}F$ and $< 140^{\circ}F$ ($60\,^{\circ}C$)
Class III:	flash point $> 140\,^{\circ}F$ ($60\,^{\circ}C$)
Class III A:	flash point $> 140\,^{\circ}F$ and $< 200\,^{\circ}F$ ($93.3\,^{\circ}C$)
Class III B:	flash point $> 200\,^{\circ}F$ ($93.3\,^{\circ}C$)

Safety regulations concerning storage and transport are specified for each danger class.

Combustible liquids are also classified according to their flash point in other national and international regulations, e.g., ADN, ADNR, ARD, GGVS, IATA, IMDG, IMO, and RID.

The following regulations must be observed when combustible solvents are stored or handled in closed spaces:

1) Prohibition of naked flames
2) Prohibition of smoking
3) Provision of adequate ventilation
4) Provision of fire-extinguishing equipment
5) Protection against spark formation due to static charges, percussion, or impact
6) Provisions covering the installation of electrical plant and equipment in explosion-harzard workshops (e.g., VDE 0165)
7) Provisions covering explosion-proof electrical equipment and material (e.g., Part 1 – VDE 0171)

Storage and filling vessels must be earthed and connected to one another so as to ensure electrical conduction during solvent transfer to avoid spark formation due to electrostatic charges. The ignition groups of the solvents should be taken into account when installing and wiring electrical fittings and equipment.

5.4. Waste

Recycling and Waste-Gas Purification. Solvent recycling is becoming increasingly important for environmental reasons. The following methods may be employed to recover a solvent from a solvent vapor–air mixture but are still uneconomical due to their high costs [148–159]:

1) Condensation on cold surfaces
2) Adsorption on a solid adsorbent, e.g., activated charcoal
3) Absorption in high-boiling liquids
4) Membrane processes [160], [161]

Removal of solvent from a solvent vapor–air mixture is nowadays even more economically efficient than recovery methods, and can be effected by [162–165]:

1) Thermal incineration
2) Catalytic incineration
3) Biofilters (biosolve method)
4) Biowashers
5) Membrane reactors

On account of the rapid poisoning of the catalyst in the catalytic incineration method, the thermal incineration has been most widely employed. The combustion heat is used, for example, to preheat the air in paint shop dryers [166], [167].

The recycling of paint coagulates and slurries has been intensively investigated [168], [169].

Waste Disposal [170], [171]. Solvent residues, solvent waste, and solvent-containing preparations should be stored only in air- and liquid-tight containers in special dumps.

Recent directives and legislation require that solvent-containing waste be properly burnt in special incinerators. Numerous directives are concerned with waste prevention and elimination. In the United States, the observance of these provisions is monitored by the EPA on the basis of the Resource Conservation and Recovery Act (RCRA) of 1976, which defines the term waste. Legislation has been strengthened through the Hazardous and Solid Waste Amendments (HSWA) of 1984 which deals with the itemization, characterization, and utilization of waste; the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, Superfund) of 1980; and the Superfund Amendments and Reauthorization Act (SARA) of 1986. The aim of this legislation is to recover and recycle the waste to the process in which it is used and thus avoid the formation of residues.

The treatment of waste in Germany is regulated by provisions (Abfallgesetz, TA Abfall, Sonderabfallbestimmungsverordnung, Abfall- und Reststoffüberwachungsverordnung) that require product manufacturers and processors to describe residues in terms of their chemical and physical properties. They also cover the transportation of waste, proof of and permission for waste disposal, prohibition of mixing wastes, and assigning appropriate treatment techniques to specific types of waste [172–175].

Waste is classified by code numbers to facilitate handling and define potential risks:

- Code No. 553 for solvent wastes, with subgroups for individual solvents
- Code No. 554 02 for solvent-containing slurries
- Code No. 555 with subgroups for paints and coating materials
- Code No. 597 03 for distillation residues

According to the TA Abfall of March 12, 1991, all solvent-containing waste must be disposed of thermally in pyrolysis units or in special waste incinerators equipped with flue-gas cleaning systems. The residues are then stored underground or in special waste dumps. Since combustion capacity is insufficient, medium- to longterm measures will have to be taken to avoid and recycle waste. Waste production has to be avoided as far as possible in the industrial and commercial sectors, instead, waste should be recycled. Any unavoidable waste should be safely disposed of (usually by combustion).

An OECD guideline on "Hazardous Waste from the Production and Use of Organic Solvents" is currently (1992) being drafted. Waste prevention, reduction, recovery, and recycling are preferred to the combustion and the biological and physicochemical treatment of unavoidable waste.

The problem of wastewater is closely coupled with the processing of solvent-containing paints, adhesives, and other preparations.

In Germany, for example, the conditions for the discharge of dangerous substances into lakes, rivers, and waterways have become more stringent due to the Wasserhaushaltsgesetz, WHG (Water Management Law) of September 23, 1986 [Bundesgesetzblatt I (1986) No. 50, p. 1529 ff.]. "Dangerous substances" are registered in a constantly updated list compiled by the Ministry of the Environment. All plants and factories that produce effluent containing dangerous substances covered by the Abwasserherkunftsverordnung, AbwHerkV (Directive Concerning the Origin of Effluents) of July 3, 1987 must satisfy the requirements of the state of the art.

The WHG lays down instructions for handling "water-hazardous" substances in § 19 g – 19 l. The substances are compiled in a catalog, published in the Ministerialblatt (ministerial bulletin) 1985 and its supplements. They are subdivided into classes (Wassergefährdungsklassen, WGK) according to their water-hazard potential:

WGK 0:	Generally not water hazardous, e.g., ethanol, acetone
WGK 1:	Slightly water hazardous, e.g., aliphatic compounds, ethylbenzene, alcohols, ketones, ethers, esters
WGK 2:	Water hazardous, e.g., aromatic compounds, dichloromethane, carbon disulfide
WGK 3:	Highly water hazardous, e.g., tetrachloroethylene

The water hazard class of mixtures is determined according to data obtained from the mixture. If such data do not exist, the component of the highest water hazard class is decisive. Paints are classed in WGK 2 on account of their solvent contents.

6. Purification and Analysis

Purification. Distillation is most commonly used for purifying solvents. Solvents with different vapor pressures can be separated from one another by fractional distillation. Azeotropic mixtures can be separated by extractive or azeotropic distillation (e.g., addition of benzene to a water – ethanol mixture), by chemical reaction of a component (e.g., addition of acetic anhydride to an ethanol – ethyl acetate mixture), or by altering the pressure during distillation.

Further methods for purifying solvents include freezing out water from solvents that are partially miscible with water, extracting water-soluble constituents from water-immiscible solvents by shaking with water, and the use of adsorbents (e.g., activated charcoal).

Analysis. Solvent purity is assessed by means of gas chromatography [176–182], physical properties, water content, evaporation residue, and acid, saponification, and hydroxyl numbers [183]. Color and smell are also evaluated.

Standardized tests are employed in the analysis of solvents (see Table 20).

Further special analytical methods are discussed in [184–187].

7. Uses

7.1. Solvents in Paints

See also → Paints and Coatings.

Composition of Paint-Solvent Mixtures. The composition of a paint-solvent mixture is governed by the application conditions, drying temperature, and drying time of the paint. The solvent mixture in a paint that undergoes physical drying at room temperature contains ca. 45 % low boilers, ca. 45 % medium boilers, and ca. 10 % high boilers.

True solvents and latent solvents are present in such a ratio that the paint dries to give a clear film without haze. Low boilers accelerate drying, whereas medium boilers and high boilers are used to produce a flawless surface. Oven-drying paints, stoving enamels, and coil coatings are applied at relatively high temperature and contain a large amount of high boilers and only a small amount of readily volatile solvents, if at all, because they may cause the paint to "boil" during stoving.

The nature of the solvents in the mixture also depends on the type of binder. In order to obtain rapid drying combined with low solvent retention, the solvent mixture should be formulated so that its solubility and hydrogen-bonding parameters lie at the boundary of the binder solubility range. On the other hand, the parameters of the solvent mixture should be similar to those of the binder to ensure satisfactory flow. Finding a sensible compromise is difficult and requires a great deal of experimental effort. It is advantageous if the non-solvents which, according to the solubility parameter concept, accelerate drying, are more volatile than the solvents, which remain behind and improve the flow [33].

The volatility and dissolution properties of the solvent mixture should be adjusted [188] so that its parameters move from the solubility boundary to the solubility center of the binder during evaporation. It must, however, be borne in mind that the solids concentration increases during evaporation of the solvent and that the paint temperature increases or decreases, thus altering the solubility range of the binders. Numerous studies have been published on the evaporation of solvent mixtures from paint films [189].

Paint Viscosity. The viscosity of a paint depends on:

1) The nature of the binder
2) The solvent composition
3) The binder concentration
4) The pigment content
5) The temperature

In homologous solvent series the paint viscosity generally increases with increasing molecular mass of the solvent. Since the solvency power of a solvent decreases with increasing molecular mass, a relationship between solvency power and paint vicosity seems likely.

Comparison of solvents from different homologous series shows, however, that the viscosity is not generally dependent on the solvency power [190], [191]. The viscosity of a binder solution is determined by diverse binder – solvent interactions [192–196]. It is also influenced by the intrinsic solvent viscosity, the degree of uncoiling of the binder, the molecular mass of the binder, hydrogen bonding between binder and solvent molecules, as well as solvation and hydrogen bonding between binder molecules and between solvent molecules. Accordingly, the viscosity of a paint is also not generally at its lowest when the solubility parameter values of the solvent mixture coincide with those at the center of a binder-solubility region [33]. A binder is most strongly uncoiled (i.e., has its maximum volume) in the center of its solubility region. Solvents that have the solubility parameters of the binder solubility center therefore often form paints with a particularly high viscosity [197], [198]. In order to obtain low-viscosity paints, solvent additives are used to displace the solubility parameters of the solvent mixture toward the boundary of the binder solubility region; however, turbidity or a sharp increase in viscosity may be expected if this boundary is exceeded. The viscosity of paints that contain alcohol solvents or binders with hydroxyl groups can be reduced by adding small amounts of non-solvents (e.g., white spirit); on dilution viscosity-increasing hydrogen bonds are apparently ruptured. Relationships between viscosity and the hydrogen bond parameters of binders and solvents are described in [199].

The viscosity η of a paint is reduced on raising the temperature according to the Arrhenius equation,

$$\frac{1}{\eta} = A\mathrm{e}^{-E/RT}$$

in which A and E are material constants [200]. Resultant sagging phenomena of the paint from vertical surfaces must be prevented by using solvents that form hydrogen bonds and by making the paint thixotropic.

Paints have widely differing viscosities that depend on their application conditions; low-viscosity paints are processed by dipping and spraying methods, while high-viscosity paints are used in casting, rolling, and hot-spraying methods. The correct choice of solvents serves to optimize the paint properties [201], [202].

Solvents in High-Solids and Waterborne Paints. In high-solids (low-solvent) paints, small amounts of auxiliary solvents are used to reduce the viscosity, as well as to optimize degassing and the flow properties [203]. Butyl acetate and butanol are mainly used to reduce the viscosity; in combination with glycol ethers and glycol ether acetates these solvents also improve flow properties and degassing. The viscosities (flow time in seconds, DIN-4 cup) of pigmented, high-solids paints after addition of 10 % of a solvent are listed below [204]:

Butyl acetate	78
Butanol	80
Ethyl glycol	86
Xylene	92
Ethyl glycol acetate	103
Butyl glycol	119
SOLVESSO 100	126
BUTOXYL	133
Ethylbutanol	138
Cyclohexanone	141
Butyl glycol acetate	148
Diacetone alcohol	169

Solvents for high-solids paints [205–207] cannot be selected according to the solubility parameter concept with the necessary degree of certainty. This is because the high-solids binders have a low mean molecular mass and are thus soluble in virtually all solvents with the exception of white spirit. Consequently, a boundary cannot be specified for the binder solubility region in the solubility parameter–hydrogen bonding parameter diagram and the influence of the solvents on the binder–solubility interactions cannot be estimated with sufficient accuracy [208].

In general it may be said that solvents of low intrinsic viscosity strongly reduce the viscosity of high-solids paints [209]. High-boiling solvents with a high solvency must also be used to obtain good flow properties [210].

Waterborne paints contain auxiliary solvents as solubilizers in amounts of 2 – 15 %, depending on the binder. These solubilizers are water-miscible solvents or solvents that become water-miscible in all proportions in the presence of the binder [211], [212]. The most important are listed below:

Glycol Ethers [213], [214]. Ethyl glycol, isopropyl glycol, propyl glycol, butyl glycol, isobutyl glycol, ethyl diglycol, butyl diglycol, 1-methoxy-2-propanol, 1-ethoxy-2-propanol, 1-isopropoxy-2-propanol, 1-propoxy-2-propanol, 1-butoxy-2-propanol.
Alcohols [215], [216]. Ethanol, propanol, isopropyl alcohol, butanol, isobutanol, *sec*-butanol, *tert*-butanol.

Butanol by itself is not miscible in all proportions with water, but its water miscibility is unlimited in the presence of paint binders. Butanol is an extremely effective solvent in waterborne paints, although it has the disadvantage of a somewhat more pungent smell than glycol ethers. The auxiliary solvents in waterborne paints promote solubilization of the binder and water, reduce the viscosity maximum that occurs on dilution with water, and yield smooth-flowing, flawless paint surfaces [217–227].

Auxiliary solvents and film-forming auxiliaries are also used as flow promoting agents in aqueous dispersions (emulsion paints). Propylene glycol acts not only as a solvent, but is hygroscopic and thus ensures a sufficiently high water content in the coating until a smooth surface has formed.

Pigment Wetting. The wetting of pigments is influenced both by the binder and the solvent. Good pigment wetting is important for pigment grinding in the finished paint product. The solubility parameters and, more commonly, hydrogen bond parameters of the binders and solvents influence pigment wetting [197], [198], [228], with the result that good or bad dispersibility, flocculation, and leafing effects may occur [33].

Blushing, Gloss, and Flow Properties. When the solvents evaporate from a paint the latter cools. At high atmospheric humidity water droplets condense if the temperature of the paint surface is below the dew point. This water is absorbed and homogeneously distributed in paints that contains solvents that are able to absorb water (e.g., ethanol or glycol ether). If the paint does not contain such solvents the water remains on the surface as a visible white haze (blushing). Blushing disappears if the paint contains solvents that form volatile azeotropes with water (e.g., aromatic hydrocarbons or butanol).

The gloss of paint coats is significantly enhanced if true solvents (high boilers) are the last solvents to evaporate in the paint formulation. Glycol ethers, in particular, improve the gloss due to their effect on the flow properties of the paints. A paint should dry to form a smooth, flat film without any surface structure as a result of the coalescence of the paint particles. Unsatisfactory paint flow leads to surface defects known as the orange-peel effect, honeycomb structure, and fish eyes. These defects may be attributed to physical factors (e.g., to a change in the surface tension of the paint during solvent evaporation) and associated eddy formation in the paint film [192], [229–232]. Rapid evaporation occurs preferentially at the film surface causing the surface tension to increase more markedly than in the interior of the film. The resultant eddies in the film must be prevented by using slowly evaporating solvents with a good solvency for the binder. Additives that reduce the surface tension, e.g., wetting agents or silicone oils, also have a beneficial effect.

Mechanical Properties and Solvent Retention. Solvents significantly influence the mechanical properties of a paint for the following reasons:

1) Solvents influence the molecular structure of the film by aligning the binder molecules or preventing ordering
2) Solvents react to some extent with reactive, multicomponent catalyzed lacquers containing a binder component and thus exert an internal flexibilizing effect
3) Solvents are retained by the paint film and exert an external flexibilizing effect

Glycol ethers have a flexibilizing action on saturated polyester resins that cross-link with melamine – formaldehyde resins; some functional groups in the melamine resin are apparently blocked by the glycol ether. The flexibilization of paint films by retention of solvents occurs in copolymer paints and has been investigated by gas chromatography [233] and radiotracer methods [234]. Dry, hardened paint films absorb solvents to varying degrees [235], [236]. Dichloromethane swells almost all paints films which is the reason for its good paint-removing action. The swelling action of aromatic hydrocarbons on polyester stoving enamels cross-linked with

melamine resin depends on the monomer composition of the saturated polyester resin [63] and the degree of cross-linking after stoving [237].

Thick-Coat Paints and Multicoat Paints. Paints for anticorrosion systems that are applied by airless methods are prepared on the basis of, for example, vinyl chloride copolymers. Thick, high-solids coats can be obtained in a few stages with short drying times between coats. The solvents should deaerate the paint quickly and produce rapid drying and good flow. These properties can only be obtained by accurately coordinating the solvent components. In the case of multicoat paints the solvent composition of the top coat must be selected such that the primer is not swollen by inwardly migrating solvents. Mild true solvents (e.g., alcohols and glycol ethers), diluents, and nonsolvents should be used for this.

7.2. Solvents in Paint Removers

Solvents used for paint removal are able to dissolve or considerably swell physically drying binders (e.g., vinyl chloride copolymers, cellulose nitrate, polyacrylates) and chemically cross-linked coatings (e.g., oil-based paints, dried alkyd resins, cross-linked polyester – melamine resins, cross-linked epoxy and isocyanate coatings) [238]. A combination of dichloromethane with low-boiling ketones or esters is particularly suitable. Small amounts of high-boiling solvents with a low volatility (e.g., tetrahydronaphthalene, solvent naphtha, methyl benzyl alcohol, or benzyl alcohol) are added to these mixtures to retard evaporation and increase the solvency. Modern paint removers do not contain chlorinated hydrocarbons, they are formulated on the basis of high boilers (e.g., dimethylformamide, dimethyl sulfoxide, propylene carbonate, and *N*-methylpyrrolidone) in combination with alcohols and aromatics, or consist of aqueous, frequently alkaline or acidic systems. See also, → Paints and Coatings, Chap. 6.

7.3. Solvents in Printing Inks

Solvents in printing inks (→ Printing Inks) must readily dissolve the binder or resin and must not attack the printing rollers [239]. Acidic or sulfur-containing solvents must not be used with copper rollers. Aliphatic and aromatic hydrocarbons that attack rubber are unsuitable for offset inks. Alcohols, glycol ethers, and glycol ether esters are most suitable for gravure and flexographic printing.

The volatility of the solvents must be adapted to the application process, the drying process, and the drying time during printing. Solvents are rarely used in offset, letterpress, and typograhical printing, whereas rapidly evaporating solvents are employed in flexographic and gravure printing.

7.4. Extraction [240–242]

The distribution of dissolved substances in two solvent phases is employed on a large scale in the industrial separation of mixtures of substances (→ Liquid – Liquid Extraction; → Liquid – Solid Extraction). Examples are the removal of unsaturated constituents from vegetable oils with furfural or methanol, the purification of animal and vegetable oils with liquid propane, and the removal of waxes from lubricants with liquid propane or ketones. Penicillin is similarly concentrated with methyl isobutyl ketone, and aqueous glycerol is purified with xylene. Preparative and analytical separations are also performed by liquid – liquid extraction. Inorganic salts can be extracted from aqueous solutions with suitable solvents, such as ethers, ketones, and esters. This method is particularly efficient for metal halides and nitrates, e.g., the separation of uranium compounds from aqueous solutions or the fractional extraction of rare earths.

7.5. Extractive Distillation [243], [244]

In extractive distillation a solvent is added to the mixture to be separated, its boiling point is higher than that of the components of the mixture. In the case of a binary mixture, the added solvent must interact more strongly with one of the components to lower its volatility. The other more volatile component can thus be distilled off, leaving the added solvent and the higher-boiling component at the bottom of the column. The added solvent (entrainer) must be miscible

with the mixture at all temperatures, concentrations, and pressures. See also → Distillation and Rectification, Chap. 6.5.

A mixture of cyclohexane (*bp* 80.8 °C) and benzene (*bp* 80.1 °C) can, for example, be separated by distillation after adding aniline, since the interaction between benzene and aniline is greater than that between cyclohexane and aniline. Azeotropic mixtures can be separated similarly by extractive distillation (e.g., water – ethanol by adding glycerol). Hydrocarbons with similar boiling points can be separated by extractive distillation in the presence of polar liquids (nitrobenzene, phenol, furfural).

7.6. Chromatography

Chromatography of a mixture on a stationary phase using a liquid eluent is a form of solid – liquid extraction (adsorption chromatography). The distribution of components between the surface of the carrier material and the solvent depends on their chemical structure and the nature of the carrier material and the migrating solvent [11], [245–247]. The solvents used in adsorption chromatography are arranged in an eluotropic series, the eluting action of the solvents increases with increasing polarity as follows: pentane, petroleum ether, hexane, heptane, cyclohexane, tetrachloromethane, trichloroethylene, benzene, dichloromethane, trichloromethane, diethyl ether, ethyl acetate, pyridine, acetone, propanol, ethanol, methanol, and water.

Liquid – liquid extraction is also possible in which distribution takes place between a liquid eluent and a liquid (generally water) that is adsorbed on the surface of the carrier material (distribution chromatography).

7.7. Solvents for Chemical Reactions

Solvents for chemical reactions must be chemically inert under the reaction conditions. The following solvents have proved suitable [241]:

1) *Hydrogenation*: alcohols, glacial acetic acid, hydrocarbons, dioxane
2) *Oxidation*: glacial acetic acid, pyridine, nitrobenzene
3) *Halogenation*: tetrachloromethane, tetrachloroethane, dichlorobenzene, trichlorobenzene, nitrobenzene, glacial acetic acid
4) *Esterification*: benzene, toluene, xylene, dibutyl ether
5) *Nitration*: glacial acetic acid, dichlorobenzene, nitrobenzene
6) *Diazotization*: ethanol, glacial acetic acid, benzene, dimethylformamide
7) *Coupling reactions of diazonium compounds*: methanol, ethanol, glacial acetic acid, pyridine
8) *Grignard reaction*: diethyl ether
9) *Friedel – Crafts reaction*: nitrobenzene, benzene, carbon disulfide, tetrachloromethane, tetrachloroethane, 1,2-dichloroethane
10) *Dehydration*: benzene, toluene, xylene
11) *Sulfonation*: nitrobenzene, dioxane
12) *Dehydrohalogenation*: quinoline
13) *Decarboxylation*: quinoline
14) *Acetal formation*: hexane, benzene
15) *Ketene condensation*: diethyl ether, acetone, benzene, xylene

The rate and course of the reaction often depend on the nature of the solvent [3], [248], [249]. Solvent effects have also been described in radical polymerizations [250].

7.8. Solvents for Recrystallization

Solvents for recrystallization should readily dissolve the substance to be purified as well as the impurities on heating; on cooling the solution the pure substance then crystallizes out, whereas the impurities remain in solution. If the temperature dependence of the solubility of the substance in the solvent is only slight, it can be precipitated by adding a non-solvent to the hot solution. The purification effect of recrystallization is greater the more slowly the solution is cooled and accordingly the more slowly the crystals form.

7.9. Solvents in Film Production

Diethyl ether – ethanol mixtures are used as solvents in the production of cellulose nitrate films. Acetone is most suitable for cellulose acetate or cellulose acetate butyrate films, and dichloromethane for cellulose triacetate films.

7.10. Solvents for Synthetic Fibers

Solvents used for the preparation of spinning solutions (dopes, → Fibers, 3. General Production Technology, Chap. 2.1.4.) should be inexpensive, easily recoverable, volatile, have as low a viscosity as possible, and should readily dissolve the high molecular mass polymers to be spun. The following solvents have proved suitable: dichloromethane – methanol for cellulose triacetate, tetrahydrofuran or carbon disulfide – acetone for non-postchlorinated poly(vinyl chloride), acetone for postchlorinated poly(vinyl chloride), and dimethyl sulfoxide or propylene carbonate for polyacrylonitrile.

7.11. Solvents for Rubber, Plastics, and Resin Solutions

Aliphatic hydrocarbons, in some cases mixed with aromatic hydrocarbons, are suitable for rubber solutions.

Plastics and resin solutions usually contain highly or moderately volatile solvents. The solutions are used for example to coat articles with a plastic, as adhesive solutions [251], as nail polish, and for textile impregnation. Esters, ketones, alcohols, or cyclic ethers are suitable depending on the intended use.

Table 14. Development of consumption of solvents in Western Europe (as percentage of total)

	1980	1986	1990	1995	2000
Oxygen-containing solvents	36.5	45	51	58	65
Aliphatics	28.5	22	20.5	19	18
Aromatics	20.5	20	19	17	15.5
Chlorinated hydrocarbons	14.5	13	9.5	6	1.5
Total consumption 10^6 t	5.1	4.75	4.7	4.15	3.3

7.12. Solvents for Degreasing

Ketones or chlorinated hydrocarbons, especially trichloroethylene, perchloroethylene, or dichloromethane, are used to degrease metals [252], [253]. The chlorinated hydrocarbons used to degrease light metals are stabilized to prevent the metal-catalyzed elimination of hydrogen chloride. The solvent mixture [254–257] for metal degreasing are being replaced by aqueous systems [258], [259] due to more stringent environmental protection requirements.

Table 15. Solubility parameters δ, dipole moments μ $(J/cm^3)^{1/2}$ and hydrogen bond parameters γ

Solvent	δ	δ_D	δ_P	δ_H	μ	γ

7.13. Solvents for Dry Cleaning

Aliphatic hydrocarbons or perchloroethylene are used for the chemical cleaning of textiles (→ Dry Cleaning, Chap. 2.). Resins are often added to the dipping baths to hydrophobize the textiles [260].

7.14. Solvents in Aerosol Cans and Dispensers

Solvents used in aerosol cans (spray cans for hair lacquer, cleansing agents, paints) must, of course, dissolve the substances that are to be sprayed. They must also be miscible with the propellants without causing the dissolved substance to precipitate. Previously, chlorofluorohydrocarbons were mainly used as propellants but they have a damaging effect on the stratospheric ozone layer and have now been largely replaced by alternatives (e.g., hydrocarbons such as butane, diethyl ether, fluorocarbons, carbon dioxide) [261].

8. Economic Aspects [262]

Solvents are mainly used for the following purposes:

1) For cleaning and degreasing: electronic components, metal surfaces, dry cleaning of textiles
2) As a raw material: for preparing other products; in the paint, adhesives, and plastics industries; for producing resin solutions
3) As a carrier or dispersion medium: pharmaceutical products, agrochemicals

Future solvent consumption is expected to decrease on account of worldwide environmental restrictions. There will be a shift from aromatic and aliphatic hydrocarbons to oxygen-containing solvents because the latter have a lower ozone formation potential and better dissolution properties. Table 14 shows the anticipated development in consumption in Europe up to the year 2000.

9. Solvent Groups

Important information and data on individual solvents are listed in the following tables:

Table 15: Solubility parameters, dipole moments, and hydrogen bond parameters
Table 16: Miscibility with water
Table 17: Azeotropes of the most important solvents
Table 18: Relationships between solubility parameter and surface tension
Table 19: Gross calorific values

9.1. Aliphatic Hydrocarbons

Aliphatic hydrocarbons, naphthas, gasoline, or paraffin hydrocarbons are chemically inert and are thus very stable solvents [263], [264]. Aliphatic hydrocarbons exhibit a good solvency for mineral oils, fatty oils (with the exception of castor oil), waxes, and paraffin. They also dissolve rubber, polyisobutene, molten polyethylene, poly(butyl acrylate), poly(butyl methacrylate), and poly(vinyl ethers). However, most other polymers, polar resins, cellulose derivatives, and most paint binders are insoluble. Resins and binders with a low polarity dissolve less readily in aliphatic hydrocarbons than in aromatic hydrocarbons.

Aliphatic hydrocarbons are subdivided according to their boiling point ranges into special boiling point hydrocarbons (SBP, DIN 51 631), white spirit (DIN 51 632), and petroleum ether (DIN 51 630) (see Tables 20 and 23).

Special boiling point hydrocarbons are used for quick-drying paints, dipping solutions, and quick-drying adhesives. Their flash point is below 21 °C, which means that they must be used in explosion-proof areas. Petroleum ether is a special petroleum distillation fraction (*bp* 40 – 60 °C), and is used as a solvent in the chemical industry.

White spirit is used predominantly in the paint industry as a solvent or diluent for oil-based, alkyd resin, chlorinated rubber, and some

vinyl chloride copolymer paints; light napththas have flash points above 21 °C. Varnish makers' and painters' (VMP) naphtha (*bp* 100 – 150 °C) is used mainly as diluent.

9.2. Cycloaliphatic Hydrocarbons

The solvency of cycloaliphatic hydrocarbons is between that of aliphatic and aromatic hydrocarbons. They have a high solvency for fats, oils, oil-modified alkyd resins, styrene-modified oils and alkyd resins, bitumen, rubber, and other polymers. Polar resins (e.g., urea --, melamine --, and phenol – formaldehyde resins), as well as alcohol-soluble synthetic resins and cellulose esters are, however, insoluble.

Cycloaliphatic hydrocarbons are miscible with most other solvents, but are insoluble in water.

Table 21. Trade marks and trade names of solvents

Solvent	Chemical name	Manufacturer
Acintene	dipentene, pinene	DRT, France
Algofrene	fluorinated hydrocarbons	Montedison
Anol	cyclohexanol	BASF

Texacar	ethylene/propylene carbonates	Texaco
Texanol	ester-alcohol	Eastman Chemical
Texsolve	aliphatic/aromatic hydrocarbons	Texaco
UCAR ester EEP	ethyl-3-ethoxypropionate	Union Carbide
Varsol	aliphatic hydrocarbons	Exxon Chemical

Cyclohexane [*110-82-7*] is a water-clear, colorless liquid with a gasoline-like smell; it is miscible with most organic solvents except methanol, dimethylformamide, and solvents of similar polarity (→ cyclohexane).

Methylcyclohexane [*108-87-2*] is similar to cyclohexane but less volatile (→ cyclohexane, chap. 7.2.).

Table 22. Abbreviations for solvents

Abbreviation	Name
BDG	butyl diglycol
BDGA	butyl diglycol acetate
BG	butyl glycol
BGA	butyl glycol acetate
BLO	butyrolactone
DAA	diacetone alcohol
DBE	dibasic esters
DEE	diethyl ether
DEG	diethylene glycol
DEK	diethyl ketone
DIBK	diisobutyl ketone
DMAC	dimethylacetamide
DMI	1,3-dimethyl-2-imidazolidinone
DMF	dimethylformamide
DMK	acetone
DPB	dipropylene glycol butyl ether
DPG	dipropylene glycol
DPM	dipropylene glycol methyl ether
DPMA	dipropylene glycol methyl ether acetate
EDG	ethyl diglycol
EDGA	ethyl diglycol acetate
EEP	ethyl 3-ethoxypropionate
EG	ethyl glycol
EGA	ethyl glycol acetate
IBA	isobutanol
IBIB	isobutyl isobutyrate
IMI	3-isopropyl-2-methylimidazole
IO	3-isopropyl-2-oxazolidinone
IP	isophorone
IPA	isopropyl alcohol
IPE	diisopropyl ether
IPG	isopropyl glycol
IPP	isopropoxypropanol
MBK	methyl butyl ketone
MDG	methyl diglycol
MEG	monoethylene glycol
MEK	methyl ethyl ketone
MG	methyl glycol
MGA	methyl glycol acetate
MHK	methyl hexyl ketone
MIAK	methyl isoamyl ketone
MIBK	methyl isobutyl ketone
MIPK	methyl isopropyl ketone
MOX	3-methyl-2-oxazolidinone
MPK	methyl propyl ketone
NBA	*n*-butanol
NMP	*N*-methyl-2-pyrrolidone
NPA	*n*-propanol
PB	butoxypropanol
PDG	propylene diglycol
PG	propylene glycol
PM	methoxypropanol
PMA	methoxypropyl acetate
PP	propoxypropanol
PTB	*tert*-butoxypropanol
SBA	*sec*-butanol
TPM	tripropylene glycol methyl ether

1,2,3,4-Tetrahydronaphthalene [*119-64-2*] (tetralin) is an aromatic-cycloaliphatic hydrocarbon. It is a colorless liquid with a naphthalene-like odor, insoluble in water, and miscible with all common organic solvents (→ Naphthalene and Hydronaphthalenes, Chap. 5.). It dissolves fats, oils, linoxyn, rubber, waxes, asphalt, bitumen, pitch, tar, phenol, naphthalene, iodine, sulfur, etc., and is used on a large scale in painting work, and in floor wax and shoe polish production. It also dissolves colophony, Congo copals, glyptal resins, coumarone resins, ketone–formaldehyde resins, and aminoplasts. It imparts good flow properties to paints and produces high-gloss, smooth film surfaces. It is autooxidative and thus acts as an oxygen carrier in drying oils.

Decahydronaphthalene [*91-17-8*] (decalin) is a colorless solvent with a pungent odor and fairly high volatility, its solvency is somewhat lower than that of tetrahydronaphthalene (→ Naphthalene and Hydronaphthalenes, Chap. 5.).

9.3. Terpene Hydrocarbons and Terpenoids

Turpentine oil [*8006-64-2*] (DIN 53 248). Only pure ethereal oil obtained from the distillation of the resinous secretion of living pine trees, and from which no valuable constituents (e.g., pinene) have been extracted, may be used as balsam terpentine oil (RAL, Sheet 848 C). All turpentine oils obtained in any other way must be specially labelled with details of their source. Oils of turpentine from different countries differ in composition. American and Greek oils contain predominantly D-pinene, whereas French, Spanish, and Portuguese oils contain L-pinene.

Balsam turpentine oil is a highly mobile liquid with a characteristic odor. On prolonged storage the boiling point falls, and resinification may subsequently occur. Turpentine oil has a good solvency for fats, oils, waxes, and hydrocarbon resins. It is miscible with ethanol and aliphatic and aromatic hydrocarbons. Its dissolution properties are better than those of white spirit. It is used in addition to white spirit in oil-based and alkyd resin paints. The higher boiling constituents of wood turpentine oil contain a large amount of terpineol and are treated as pine oil. Pine oil is used as a high-boiling solvent in stoving enamels.

Root turpentine oil is obtained by steam distillation of wood chips and shavings with a high resin content. Its properties are similar to those of sulfite cellulose oil of turpentine, which occurs in wood pulp production. Root turpentine oil is a colorless liquid with similar properties to balsams turpentine oil.

Wood oil is obtained by dry distillation of chips and shavings with a high resin content. It is a yellow, acidic liquid with an unpleasant odor. On exposure to air and also after purification it becomes discolored and the odor becomes more unpleasant. It is only suitable as a solvent for dark paints and lacquers.

Terpenoids are obtained by distillation of turpentine oils. α-Pinene [*80-56-8*] is used in the preparation of camphor. Higher-boiling constituents include pine oil [*8000-41-7*] (terpineol; trade names: Depanol, Solvenol, Terposol, Yarmor). Hydroterpine is prepared by hydrogenation of pine oil and is used as a substitute for turpentine oil. Terpenoids are used as high-boiling solvents in oil-based and alkyd resin paints. Dipentene [*138-86-3*] prevents skin formation in air-drying paints. D-Limonene [*5989-27-5*] see [265].

9.4. Aromatic Hydrocarbons

Compared to aliphatic hydrocarbons, aromatic hydrocarbons (DIN 51 633) have a higher solvency for oils, castor oil, oil-modified alkyd resins,styrene-modified oils and alkyd resins,saturated polyester resins, polystyrene, poly(vinyl ethers), polyacrylate and polymethacrylate esters, poly(vinyl acetate), vinyl chloride and vinyl acetate copolymers,and many low-polarity resins.

Aromatic hydrocarbons are used as diluents in solutions of cellulose nitrate, cellulose esters, and ethers with true solvents such as esters and ketones. Rubber, polyisobutene, and molten polyethylene also dissolve in them. Poly(vinyl chloride), solid polyethylene, polyamides, and shellac are, however, insoluble or only swell.

Toluene [*108-88-3*] is mainly used in cellulose nitrate lacquers; in heat- curing paints based on urea--, melamine--, or phenol–formaldehyde resins; in alkyd resin paints; and in paints based on chlorinated rubber, polystyrene, polyacrylates, or poly(vinyl acetate) (→ Toluene).

Mixtures of toluene with esters are used to dissolve vinyl chloride copolymers and postchlorinated poly(vinyl chloride) [266].

Xylene (mixture of *o*-, *m*-, and *p*-isomers, [*56004-61-6*], [*108-38-3*], [*41051-88-1*]) generally contains very small amounts of toluene and larger amounts of ethylbenzene (→ Xylenes). Xylene is the most important aromatic solvent in the paint industry. It dissolves poly(vinyl acetate) only in combination with alcohols or glycol ethers, but is otherwise similar to toluene as regards dissolution properties.

Ethylbenzene [*100-41-4*] (phenylethane) has a water- clear appearance and characteristic odor (→ Ethylbenzene). It is miscible with practically all organic solvents, but is insoluble in water. Ethylbenzene is of limited importance as a paints solvent. Its main use is as an industrial starting material for the production of styrene by catalytic dehydrogenation (→ Styrene). Catalytic oxidation of ethylbenzene with air in the presence of heavy-metal oxides yields acetophenone and phenylmethylcarbinol. It also improves the antiknock properties of fuels for Otto engines.

Cumene [*98-82-8*] is the principal constituent of heavy naphtha which is the feedstock for phenol and acetone synthesis by the Hock process (→ Hydrocarbons, Chap. 3.7.). It is also a byproduct in the production of sulfite pulp.

Styrene [*100-42-5*] is a colorless liquid that acts as a solvent for unsaturated polyester resins (→ Styrene). Styrene is stabilized by the manufacturer to avoid polymerization on storage. Feedstock for chemical syntheses (polymers and copolymers, styrene-modified alkyd resins and oils).

9.5. Chlorinated Hydrocarbons

Chlorinated hydrocarbons have a better solvency than the corresponding nonchlorinated compounds for most resins, polymers, rubber, waxes, asphalt, and bitumen. Chlorinated hydrocarbons are miscible with other organic solvents, but are insoluble in water. They have a sweetish odor. Increasing the number of chlorine substituents reduces the combustibility and improves the solvency, but also increases the toxicity.

All chlorinated hydrocarbons may decompose under the action of light, air, heat, and water. Decomposition can be reduced but not completely prevented by adding stabilizers. On account of their health hazard, some chlorinated hydrocarbons may no longer be used as conventional solvents, e.g., tetrachloromethane, tetrachloroethane, and pentachloroethane. Dichloromethane, trichloroethylene, perchloroethylene, and 1,1,1-trichloroethane are increasingly being replaced for reasons of industrial hygiene and environmental protection, particularly of water.

Dichloromethane [*75-09-2*] (methylene chloride) is a colorless, highly volatile, neutral liquid with a characteristic odor (→ Chlorinated Hydrocarbons, Chap. 1.). It is insoluble in water but miscible with organic solvents. It has a very good solvency for many organic substances, such as fats, oils, waxes, and resins. Bitumen, rubber, chlorinated rubber, polystyrene, postchlorinated poly(vinyl chloride), vinyl chloride copolymers, polyacrylates, and cellulose esters are also soluble. The solubility spectrum can be expanded by adding other solvents. A mixture of methanol or ethanol and dichloromethane is a good solvent for cellulose ethers and acetyl cellulose. Cellulose nitrate is, however, insoluble.

Dichloromethane is used as a noncombustible solvent and extractant for oils, fats, waxes, fish oil, etc. from industrial and animal products, as well as caffeine, hops, castor oil, cocoa butter, and ethereal oils from substances of plant origin. It is used in the deparaffination of petroleum and the azeotropic dewatering of solvents. Dichloromethane is a constituent of paint-removal pastes and baths, but is increasingly being replaced by aqueous systems. It is used as a solvent in the production of cellulose-acetate-based or cellulose-acetobutyrate-based films and is employed industrially in the leather, metal, rubber, adhesives, and plastics industries.

Trichloromethane [*67-66-3*] (chloroform) is a solvent having a powerful narcotic effect and is not widely used (→ Chlorinated Hydrocarbons, Chap. 1.).

Tetrachloromethane [*56-23-5*] (carbon tetrachloride, "Tetra"), is a colorless, neutral, nonflammable liquid (→ Chlorinated Hydrocarbons, Chap. 1.). It is toxic and forms phosgene, hydrogen chloride, and chlorine when heated. It dissolves fats, oils, resins and waxes, but not poly(vinyl acetate). Tetrachloromethane is used

in the production of rubber-adhesive solutions, for diluting sulfur monochloride in rubber vulcanization, and in the leather and shoe industries.

1,2-Dichloroethane [*107-06-2*] (ethylene chloride) is one of the most stable chlorinated hydrocarbons, with a good solvency for fats, oils, resins, rubber, bitumen, asphalt, and tar (→ Chlorinated Hydrocarbons, Chap. 2.3.). Highly toxic, the odor threshold is higher than the MAK value. 1,2-Dichloroethane is used in the production of building protection agents, roofing felts, and cold asphalt. It is used as an extracting agent for alkaloids and ethereal oils.

1,1,2,2-Tetrachloroethane [*79-34-5*] is a good solvent for resins, rubber, and cellulose acetate (→ Chlorinated Hydrocarbons, Chap. 2.7.). It is used only to a limited extent on account of its potential health hazard.

1,1,1-Trichloroethane [*71-55-6*] (methylchloroform) is insoluble in water, but miscible with organic solvents (→ Chlorinated Hydrocarbons, Chap. 2.4.). It dissolves fats, oils, resins, waxes, bitumen, and asphalt. It is used to degrease metals; as a solvent in the paint, adhesives, and plastics industries; as well as an extracting agent for fats and ethereal oils. It is being increasingly replaced for environmental protection reasons by other systems.

1,2-Dichloroethylene [*75-35-4*] (vinylidene chloride) is a highly volatile liquid with a low flammability although the hot vapors can ignite (→ Chlorinated Hydrocarbons, Chap. 3.2.).

Trichloroethylene [*79-01-6*] ("Tri") is insoluble in water, but is miscible with organic solvents (→ Chlorinated Hydrocarbons, Chap. 3.4.). It dissolves fats, oil, waxes, rubber, and many resins; it is used as a solvent and extracting agent. In paints, trichloroethylene raises the flash point, and is used as a solvent in paint removal pastes. It is increasingly being replaced by other systems for environmental protection reasons.

Perchloroethylene [*127-18-4*] (tetrachloroethylene, "Per") is a colorless, water-insoluble, nonflammable solvent having a very good solvency for greases, fats, waxes, oils, bitumen, tar, and many natural and synthetic resins (→ Chlorinated Hydrocarbons, Chap. 3.5.). It is used in chemical cleaning systems, to degrease light and heavy metals, to degrease pelts and leather (tanning), extraction of animal and vegetable fats and oils, and textile dyeing (solvent for dye baths). It is also used in the preparation of secondary chemical products (fluorinated hydrocarbons, trichloroacetic acid, etc.). Perchloroethylene is increasingly being replaced by other systems for environmental protection reasons.

1,2-Dichloropropane [*78-87-5*] is a solvent for bitumen, asphalt, and tar in the production of road-surfacing materials, building protective agents, and roofing felts (→ Chlorinated Hydrocarbons, Chap. 4.2.).

Chlorobenzene [*108-90-7*] is a colorless, neutral liquid with a weak, benzene-like odor (→ Chlorinated Hydrocarbons, Chap. 8.1.). It is insoluble in water and miscible with organic solvents. Chlorobenzene has a good solvency for fats, oils, resins, polymers, binders, rubber, and chlorinated rubber. Cellulose ethers dissolve in the presence of small amounts of alcohols; cellulose nitrate is insoluble. Chlorobenzene is a solvent in the production of bitumen and asphalt coatings for building protection.

9.6. Alcohols

On account of their hydroxyl groups alcohols (DIN 53 245) differ from aliphatic, aromatic, and chlorinated hydrocarbons by having a higher polarity and a stronger tendency to form hydrogen bonds. The relationship between the nonpolar hydrocarbon chain and the hydroxyl group is decisive for the solvency of alcohols [267]. Lower alcohols accordingly exhibit a pronounced solvency for strongly polar resins such as shellac, copal, glyptal resins, urea --, melamine --, and phenol – formaldehyde resins, cellulose nitrate, slightly ethylated ethyl cellulose, and poly(vinyl acetate). Lower alcohols are, however, poor solvents for nonpolar substances such as fats, oils, oil-modified alkyd resins, styrene-modified oils, and hydrocarbon resins.

The solvency for polar substances decreases with increasing hydrocarbon chain length, propanol and higher alcohols are therefore no longer particularly good solvents for cellulose nitrate and poly(vinyl acetate). Higher alcohols are mainly used as diluents, their solvency is substantially improved by combination with the corresponding acetate esters. On account of their gentle dissolution properties, higher alcohols are

highly suited for topcoats that are applied to a primer; the primer is not softened and lifted by these alcohol solvents. In the painting of plastics, alcohols produce only weak superficial swelling of the plastic, resulting in good adhesion without softening of the plastic. In the roller coating of paper alcohols prevent the rubber rollers from swelling, and bleeding of the coating material into the paper, high-gloss prints and paper coatings are therefore obtained.

Methanol [*67-56-1*] (methyl alcohol) is a clear, colorless liquid with a characteristic odor (→ Methanol). It is hygroscopic and miscible in all proportions with water as well as with many organic solvents. It is less soluble in fats and oils, and is only partially miscible with aliphatic hydrocarbons. Numerous inorganic substances (e.g., many salts) are soluble in methanol. Methanol has a good solvency for polar resins, cellulose nitrate, and ethyl cellulose. However, oil-modified alkyd resins and polymers, with the exception of poly(vinyl acetate), poly(vinyl ethers),polyvinylpyrrolidone and polymethacrylamide, are insoluble.

Methanol is used for methylation, and is the alcohol most easily esterified. It is used in the preparation of formaldehyde and methyl esters (e.g., dimethyl terephthalate, methyl methacrylate, methyl formate). It is also employed as a solvent for cellulose nitrate, colophony, shellac, and urea resins in the explosives and paint industries. Furthermore, it is used as an antifreeze, fuel, and extracting agent. Methanol is toxic although cases of poisoning are extremely rare if it is correctly used.

Ethanol [*64-17-5*] (ethyl alcohol) is available as an ethanol – water azeotrope and in anhydrous form. Both forms are supplied completely or partially denatured. Complete denaturation is effected by adding methyl ethyl ketone. Toluene, petroleum ether, and special gasolines are usually used for partial denaturation.

Ethanol is a colorless, clear liquid with a characteristic, pleasant odor (→ Ethanol). It is miscible in all proportions with water and readily miscible with many organic solvents (e.g., ethers, hydrocarbons, acids, esters, ketones, carbon disulfide, glycols, and other alcohols). Ethanol dissolves castor oil, cellulose nitrate with a low nitrate content, polar resins, and polymers. Ethanol in combination with aromatic compounds dissolves cellulose acetate. Mixtures of ethanol, aromatic hydrocarbons, and water are good solvents for some polyamides. Ethanol is extensively used in the chemical and pharmaceutical industries. It is employed as a raw material for many chemical syntheses (e.g., esterification, as an ethylating agent, and reaction medium). Ethanol is an excellent solvent, diluent, and extracting agent for fats, oils, paints, and natural substances, such as aroma substances, fragrances, perfumes, and pharmaceutical preparations. On account of its pleasant odor and weak substrate solvency it is employed in the formulation of paper and plastics coatings and paints, as well as for flexographic inks. It is also used in the form of methylated spirit for cooking or heating.

Propanol [*71-23-8*] (1-propanol) is a colorless liquid that is soluble in water and miscible with organic solvents (→ Propanols). It has better dissolution properties than ethanol for fats and oils, and dissolves polar resins in the same way as ethanol. Cellulose nitrate and poly(vinyl acetate) are, however, almost insoluble. For economic reasons propanol is of only limited use as a solvent, and is a starting material for esters.

Isopropyl alcohol [*67-63-0*] (2-propanol, isopropanol) is a colorless liquid that is miscible in all proportions with water and with commonly used organic solvents (→ Propanols). It forms binary and ternary azeotropes with water and many organic solvents.

Isopropyl alcohol is extensively used in cosmetics, particularly for hair and skin lotions, and in pharmacy for preparations intended for external use. A further large area of use is the paint and printing ink industry. Isopropyl alcohol is added to fuels to prevent the icing up of the carburetor and increase the octane number. It is an important feedstock for the chemical industry, for example, in the production of acetone (particularly in the United States), esters, plasticizers, and ethers. Isopropyl alcohol is also important as a solvent (e.g., for recrystallization and extraction) and as a moistening agent for cellulose nitrate. It is furthermore used in the aerosol sector.

Butanol [*71-36-3*] (1-butanol) is a colorless neutral liquid that has a limited miscibility with water and a characteristic odor (→ Butanols). It is miscible with organic solvents. Butanol has a high solvency for most known natural and synthetic resins, fats, oils, linseed oil, saturated

polyesters, and poly(vinyl acetate). It considerably increases the dilutability of cellulose nitrate solutions with non-solvents. Cellulose esters, cellulose ethers, chlorinated rubber, poly(vinyl chloride), vinyl chloride copolymers, and polystyrene are not dissolved by butanol.

Butanol is one of the most important additives in the production of cellulose nitrate lacquers. It ensures haze-free drying and prevents blushing of drying lacquer films. Butanol improves not only the flow of cellulose nitrate lacquers but also acts as a solubilizer between the individual lacquer constituents. It is used to prevent stringing in the production of spirit varnishes. Although most alkyd resins are only sparingly soluble in butanol, even small additions of butanol to alkyd resin or oil-based paints considerably decrease viscosity and improve flow and coatability. Butanol is used in electrostatically sprayed paints to regulate the conductivity. It can be employed to a limited extent as a diluent in vinyl chloride copolymers. Butanol serves as a viscosity-reducing auxiliary solvent in waterborne paints and prevents foaming of colorants (e.g., in the paper industry). It is suitable for moistening cellulose nitrate wool and is used to a large extent as a feedstock in the production of plasticizers and urea – and melamine – formaldehyde resins.

Isobutanol [*78-83-1*] (2-methyl-1-propanol) is a colorless, neutral liquid with a characteristic odor (→ Butanols). It exhibits limited miscibility with water. Most organic solvents are miscible in practically all proportions with isobutanol. Isobutanol readily dissolves most natural and synthetic resins. Waxes dissolve satisfactorily only on heating. Cellulose esters and ethers, natural rubber, neoprene, chlorinated rubber, and polymers such as polystyrene and poly(vinyl chloride) are insoluble in isobutanol.

Isobutanol prevents blushing in drying paint films, and also improves flow and gloss. When added in amounts of 5 to 10 % it reduces the viscosity of oil-based paints, alkyd paints, and cellulose nitrate lacquers. Isobutanol can replace butanol as a moistening agent for cellulose nitrate. It is also used in the production of spirit varnishes and printing inks, and as a raw material for the production of plasticizers.

sec-Butanol [*78-92-2*] (2-butanol) has a peppermint-like odor and a considerably higher water solubility than butanol (→ Butanols). It is used to a limited extent as a solvent, e.g., in paint-removal pastes, spirit varnishes, and printing inks. On account of its good water absorption it is also suitable as a cosolvent in waterborne paints.

tert-Butanol [*75-65-0*] (2-methyl-2-propanol) is a colorless liquid that solidifies at room temperature (→ Butanols). It is soluble in most organic solvents such as alcohols, ethers, ketones, esters, and hydrocarbons. It is miscible in all proportions with water. The azeotrope with water is a liquid at room temperature.

tert-Butanol is widely used as a solvent and solubilizer because of its extremely high resistance to oxidizing agents and halogens in comparison with other alcohols. On account of its good solvency for waxes it is used as a wax remover and as an additive for the deparaffination of oils. *tert*-Butanol is widely used as an alkylating agent for aromatic compounds and phenols, isomerization of the *tert*-butyl group does not occur. *tert*-Butanol is employed in the preparation of *tert*-butyl hydroperoxides, which are used as polymerization catalysts. It also acts as a stabilizer in chlorinated hydrocarbons and as a denaturing agent for ethanol. *tert*-Butanol is used in the production of aromas (including *tert*-butyl esters and *tert*-butyl aromatics) and antioxidants.

Amyl Alcohol. Of the eight isomers of amyl alcohol, three have asymmetrically-substituted carbon atoms (→ Pentanols). The amyl alcohol obtained from fusel oil consists of 3-methylbutanol [*123-51-3*] (isoamyl alcohol) and 2-methylbutanol [*137-32-6*] (active amyl alcohol); the mixture is sold as fermentation amyl alcohol or technical grade isoamyl alcohol. Isoamyl alcohol has similar dissolution properties to butanol. It is used as a solvent, and as a raw material for acetate esters, plasticizers, and lubricant components. Amyl alcohol containing *n*-pentanol (1-Pentanol [*71-41-0*]) as the principal constituent is used on a small scale as a solvent, like butanol. It has a better oil solubility and is therefore used as an additive in lubricating and hydraulic oils. It is used as an extracting agent for uranium salts and bituminous constituents of coal tar. It also serves as a raw material in the production of plasticizers and amyl xanthogenates (flotation auxiliaries for sulfidic ores). Pentasols are commercially available mixtures of primary and secondary pentanols.

Hexanol. The most important isomers are hexanol [*111-27-3*], 2-ethyl-1-butanol [*97-95-0*] and methylisobutylcarbinol [*108-11-2*](4-methyl-2-pentanol) (→ Alcohols, Aliphatic, Chap. 2.4.1.). Hexanol is a high boiler and is used to improve the flow and surface properties of paints; it is also used as a solvent for fats, waxes, and dyes.

2-Ethylhexanol [*104-76-7*] is a colorless, waterwhite liquid with a characteristic odor (→ 2-Ethylhexanol). It is practically insoluble in water, but is miscible with all usual organic solvents. It is a good solvent for many vegetable oils and fats, for some dyes, and for many synthetic and natural paint raw materials.

2-Ethylhexanol is esterified to produce plasticizers for various uses. The esters of 2-ethylhexanol with phthalic, adipic, azelaic, and phosphoric acid are particularly important. Maleate and acrylate esters are used in copolymerization for the internal plastification of copolymers. Di-2-ethylhexyl esters of adipic, sebacic, and decanedicarboxylic acids are base oils used for the production of synthetic, thermally-stable lubricants, in particular for jet engines and gas turbines. 2-Ethylhexyl sulfate and diethylhexyl sulfosuccinate are used as wetting and leveling agents in the textile industry. Ethoxylates of this alcohol are used as raw materials for emulsifiers, detergents, and cleansing agents. Esterification with hydrochloric acid yields 2- chloro-2-ethylhexane, which is used in the production of tin- containing stabilizers and as an intermediate for introducing the 2-ethylhexyl group into other compounds. 2-Ethylhexanol is a defoaming agent for aqueous systems in the paper, ceramics, and textile industries. It also serves as a grinding auxiliary for pigments, acts as a surface impregnation agent, and facilitates the dispersion of pigments in nonaqueous solvents. As a high-boiling solvent, small amounts of 2-ethylhexanol are added to stoving enamels to improve flow and gloss formation.

Benzyl alcohol [*100-51-6*] is miscible with organic solvents apart from aliphatic hydrocarbons (→ Benzyl Alcohol). It dissolves cellulose esters and ethers, fats, oils, alkyd resins, natural and synthetic resins, and colorants. Polymers – with the exception of lower poly(vinyl ethers) and poly(vinyl acetates) – are not dissolved. Small amounts of benzyl alcohol improve the flow and gloss paints, delay the evaporation of other solvent components, and have a plasticizing effect in physically drying paints. It is used in ballpoint pen inks. Benzyl alcohol reduces the viscosity in two-pack epoxy resin systems.

Methylbenzyl alcohol [*98-85-1*] (1-phenylethanol, 1-phenylethyl alcohol, phenylmethylcarbinol) is an almost colorless, neutral liquid that has limited miscibility with water and a weak, bitter, almond-like odor. It has a high solvency for alcohol-soluble cellulose nitrate, cellulose acetate, and cellulose acetobutyrate; for many natural and synthetic resins; and for fats and oils. In contrast to benzyl alcohol, it is miscible with white spirit.

Methylbenzyl alcohol can be used like benzyl alcohol, and can be employed advantageously in stoving enamels. In cellulose nitrate and acetyl cellulose lacquers methylbenzyl alcohol helps to improve flow and film formation and prevents blushing at relatively high atmospheric humidity levels. It has also proved to be a useful additive in paint-removal agents on account of its dissolution properties and long evaporation time. The solvency of methylbenzyl alcohol for colorants is similar to that of benzyl alcohol.

Cyclohexanol [*108-93-0*] has a camphor-like odor with a water solubility of 2 %. It is miscible with other solvents and dissolves fats, oils, waxes, and bitumen, but not cellulose derivatives (→ Cyclohexanol and Cyclohexanone).

Cyclohexanol is used in cellulose nitrate combination lacquers and oil-based paints. It delays drying, prevents blushing, and improves flow and gloss. In topcoats and clear varnishes, cyclohexanol can prevent undesirable dissolution of the primer coats. Cyclohexanol is used to remove paraffin from mineral oil; as a solvent in waxing, cleansing, and polishing agents; and as a wetting agent for spray liquids.

Methylcyclohexanol [*583-59-5*] is marketed as a mixture of isomeric methylcyclohexanols with a camphor-like odor that is insoluble in water but miscible with all organic solvents (→ Cyclohexanol and Cyclohexanone, Chap. 8.3.). Its dissolution properties are similar to those of cyclohexanol. On account of its fat-dissolving properties, methylcyclohexanol improves the adhesion of paints to articles that cannot be completely degreased before being painted.

3,3,5-Trimethylcyclohexanol is a cycloaliphatic alcohol that is available as a mixture of *cis – trans* isomers [*933-48-2*], [*767-54-4*] or in its *cis* form (→ Cyclohexanol and Cyclohexanone, Chap. 8.4.). Trimethylcyclohexanol is insoluble in water, but miscible in all proportions with most organic solvents. It has an odor reminiscent of menthol and readily dissolves waxes, resins, fats, and oils. Trimethylcyclohexanol is used in the production of special plasticizers. Bis (trimethylcyclohexyl) phthalate is for example a "hard" plasticizer for poly(vinyl chloride) with favorable elasticity and extracting properties. Trimethylcyclohexanol esters of salicylic acid act as UV absorbers and are used in sunscreen oils. The esters of mandelic acid are spasmolytics, the ester of *cis*-trimethylcyclohexanol being said to have a lower toxicity. The esters formed from trimethylcyclohexanol and polychlorophenoxyacetic acids are intermediates in the preparation of synthetic hormones. Trimethylcyclohexanol is used under the name homomenthol as a substitute for camphor and menthol. Trimethylcyclohexanol is used in the rubber industry on account of its ability to coagulate latex. It also acts as an antifoaming agent (e.g., in hydraulic fluids, textile soaps, and emulsion paints). Oxidation of trimethylcyclohexanol with nitric acid yields trimethyladipic acid, a starting product in the production of plasticizers, lubricants, dinitriles, diamines, glycols, and diisocyanates.

Furfuryl alcohol [*98-00-0*] is a colorless liquid that dissolves cellulose nitrate and many other paint binders (→ Furan and Derivatives, Chap. 4.).

Tetrahydrofurfuryl alcohol [*97-99-4*] is a colorless liquid with a weak odor that is miscible with water and organic solvents except aliphatic hydrocarbons. It dissolves cellulose nitrate and acetate, chlorinated rubber, shellac, resin esters, and many other binders (→ Furan and Derivatives, Chap. 7.).

Diacetone alcohol [*123-42-2*] (4-hydroxy-4-methyl-2-pentanone) is an almost odorless ketone alcohol that is weakly acidic as a result of rearrangement to the enol form (→ Acetone, Chap. 11.2.). It is miscible with water and organic solvents except aliphatic hydrocarbons. It acts as a good solvent for cellulose esters and ethers, alcohol-soluble resins, castor oil, and plasticizers. Poly(vinyl acetate) and chlorinated rubber are partially dissolved or swollen. Polystyrene, poly(vinyl chloride), vinyl chloride copolymers, damar resins, resin esters, rubber, bitumen, mineral oils, ketone resins, and maleate resins are insoluble. Diacetone alcohol is used as a high boiler in stoving enamels to improve flow and gloss.

9.7. Ketones

See also → Ketones.

The ketones used as solvents are water clear, highly mobile liquids having a characteristic odor (DIN 53 247). They are highly volatile and chemically very stable. On account of the carbonyl group ketones are hydrogen acceptors and have an outstanding solvency. The lower ketones dissolve polar resins, fats, oils, and less polar substances. The higher ketones have a more pronounced hydrocarbon character and are particularly good solvents for nonpolar resins, polymers, and copolymers.

Acetone [*67-64-1*] (2-propanone, dimethyl ketone) is miscible with water and organic solvents (→ Acetone). It has excellent solvency for cellulose esters and ethers, cellulose ether esters, ketone resins, ketone–formaldehyde resins, vinyl chloride copolymers, polyacrylates, polystyrene, chlorinated rubber, fats, natural and synthetic oils, and resins. Poly(vinyl chloride) and poly (methyl methacrylate) are swollen. Polyacrylonitrile, polyamides, and rubber are insoluble. Acetone is used as a highly volatile solvent in fast-drying cellulose lacquers, in adhesives, as an extracting agent and detergent, as a cellulose nitrate swelling agent in the production of smokeless gun powder, as a solvent in the production of acetate silk and cellulose acetate films. It is a solvent for acetylene in steel cylinders (dissolved acetylene).

Methyl ethyl ketone [*78-93-3*] (MEK, 2-butanone) has a similar solvency to acetone (→ 2-Butanone). Cellulose acetate is only slightly soluble, natural and synthetic waxes are insoluble. Methyl ethyl ketone is often used instead of ethyl acetate in paints (especially in wood paints), although its more pungent odor mitigates against its widespread use.

Methyl propyl ketone [*107-87-9*] (MPK, 2-pentanone) and *methyl isopropyl ketone*

[*563-80-4*] (MIPK, 3-methyl-2-butanone) are comparable to methyl ethyl ketone, but have a somewhat lower solvency (→ Ketones, Chap. 2.1.). They are more expensive than methyl ethyl ketone and are therefore of only minor importance as solvents.

Methyl butyl ketone [*591-78-6*] (MBK, 2-hexanone) is slightly soluble in water, miscible with organic solvents. Being a medium boiler it dissolves cellulose nitrate, vinyl polymers and copolymers, and natural and synthetic resins. It increases the dilutability with non-solvents and diluents. As a paint solvent, methyl butyl ketone is important only in hot-spraying and coil-coating paints. It has a very low MAK value and is recommended as a solvent because it is photochemically inactive and does not, therefore, contribute to the formation of "photosmog."

Methyl isobutyl ketone [*108-10-1*] (MIBK, 4-methyl-2-pentanone) is a colorless liquid with a sweet odor (→ Ketones, Chap. 2.2.). It is partially miscible with water, but is completely miscible with organic solvents.

Methyl isobutyl ketone is a solvent for many natural and synthetic resins such as cellulose nitrate, poly(vinyl acetate), vinyl chloride copolymers, epoxy resins, most acrylic, alkyd, ketone, coumarone and indene resins, aminoplasts, phenoplasts, rubber and chlorinated rubber, colophony, colophony esters, elemi, manila and damara (dewaxed) resins, gum sandarac and copal esters, fats, and oils. Methyl isobutyl ketone has a poor solvency, however, for most poly(vinyl acetate) resins, poly(vinyl chloride), cellulose esters and ethers, shellac, and natural waxes. Methyl isobutyl ketone is used in the paint industry as a universal medium boiler. It imparts good flow and gloss properties to cellulose nitrate lacquers, improves blushing resistance, and permits the production of highly concentrated solutions containing high proportions of inexpensive diluents. In combination with alcohols and aromatics, methyl isobutyl ketone is an important constituent of practically all epoxy resin paint formulations. Being a good solvent for low molecular mass PVC and vinyl chloride copolymers, it is used to prepare low-viscosity solutions with a high dilutability for aromatic hydrocarbons. Methyl isobutyl ketone is used as a medium-boiling component in, for example, the production of stamping varnishes for steel, tinplate sheet metal, or aluminum, as well as for printing PVC films. Methyl isobutyl ketone reduces the viscosity of alkyd resin paints and is used in all types of acrylic paints. It has proved very useful as an anhydrous and hydroxyl group-free solvent in polyurethane paints.

Methyl isobutyl ketone is advantageously used for the preparation of pesticide concentrates, including natural (pyrethrin) and synthetic insecticides and herbicides. It is a versatile extracting agent and is used to dewax mineral oils, and in the refining of tall oil, and the purification of stearic acid. Methyl isobutyl ketone is a particularly important extracting agent for metals and metal chlorides as well as for separating niobium and tantalum ores. It plays an important role in the purification and extraction of penicillin and other antibiotics. Methyl isobutyl ketone is used for the concentration of aqueous formaldehyde solutions by azeotropic distillation under reduced pressure. Isopropyl alcohol can be freed from ethanol or butanol by extractive distillation with methyl isobutyl ketone. Finally, a mixture of equal parts of methyl isobutyl ketone, ethyl acetate, and gasoline (*bp* 74.5 –79.5 °C) is used as a denaturing agent for ethanol.

Methyl isobutyl ketone has become increasingly important as a chemical feedstock. The oxime is used as an antiskinning agent in oxidatively drying paints, and the peroxide is used to cure unsaturated polyester resins. Methyl isobutyl ketone is an intermediate in the preparation of imidazolones and acetal esters. It is also used to block amines (ketimines) that act as moisture-initiated latent epoxy resin hardeners. Finally, alkaline autocondensation at elevated temperature yields higher molecular mass products that are employed as fragrances and perfumes.

Methyl amyl ketone [*110-43-0*] (MAK, 2-heptanone) and *methyl isoamyl ketone* [*110-12-3*] (MIAK, 5-methyl-2-hexanone) are high boilers with good solvency (→ Ketones, Chap. 2.5.). They are comparable to methyl isobutyl ketone as regards dissolution properties.

Ethyl amyl ketone [*541-85-5*] (EAK, 5-methyl-3-heptanone) is insoluble in water, but miscible with organic solvents (→ Ketones, Chap. 3.5.). It is a high boiler with good solvency and improves the flow properties of paints.

Dipropyl ketone [*110-43-0*] (DPK, 4-heptanone) is a high boiler with a sweet odor.

Diisopropyl ketone [*565-80-0*] (DIPK, 2,4-dimethyl-3-pentanone) is a high-boiling solvent used in the production of cellulose nitrate emulsion lacquers for coating leather, chlorinated rubber paints, and diluents for poly(vinyl chloride) organosols [268] (→ Ketones, Chap. 3.2.).

Diisobutyl ketone (DIBK) is a colorless, low-viscosity liquid, consisting of a mixture of two isomeric dimethyl heptanones (2,6-dimethyl-4-heptanone [*108-83-8*] and 2,4-dimethyl-6-heptanone [*19549-80-5*]) (→ Ketones, Chap. 3.3.). It is practically immiscible with water, but is miscible in all proportions with all common organic solvents. It is a high boiler with good solvency properties for cellulose nitrate, vinyl resins, waxes, and many natural and synthetic resins.

Diisobutyl ketone is used as a high boiler in cellulose nitrate lacquers. It acts as a leveling agent and has outstanding properties as a solvent for cellulose nitrate emulsion lacquers used to coat leather. Diisobutyl ketone is used as a solvent for vinyl chloride copolymers and as a dispersant for poly(vinyl chloride) organosols. It also serves as an extracting agent and feedstock for chemical syntheses.

Mesityl oxide [*141-79-7*] (4-methyl-4-penten-2-one) has a strong, peppermint-like odor (→ Ketones, Chap. 5.3.). It is insoluble in water, but miscible with organic solvents. It has a good solvency for cellulose nitrate, vinyl chloride and vinyl ether copolymers, polyacrylates, and many resins.

Cyclohexanone [*108-94-1*] (Hexanone) is insoluble in water, miscible with organic solvents (→ Cyclohexanol and Cyclohexanone). It is a high boiler with very good solvency for cellulose nitrate, cellulose ethers and esters, colophony, shellac, alkyd resins, natural and synthetic resins, chlorinated rubber, rubber, vinyl polymers and copolymers, polystyrene, ketone and ketone–formaldehyde resins, fats, oils, waxes, blown oils, and bitumen. It is used in paints and leather lacquers [269].

Methylcyclohexanone [*1331-22-2*] is an industrial isomer mixture. It is comparable to cyclohexanone as regards solvency and miscibility, but does not dissolve cellulose acetate (→ Cyclohexanol and Cyclohexanone, Chap. 8.3.).

Dimethylcyclohexanone is an industrial, high-boiling mixture of *cis* and *trans* isomers; [*54396-54-2*] and [*54396-55-3*], respectively. It is comparable to methylcyclohexanone as regards solvency and miscibility.

Trimethylcyclohexanone [*873-94-9*] (TMC-one, 3,3,5-trimethylcyclohexanone) is a saturated cyclic ketone (→ Cyclohexanol and Cyclohexanone, Chap. 8.4.). It is a colorless high boiler with an aromatic odor reminiscent of menthol. Trimethylcyclohexanone is only moderately miscible with water, but is miscible in all proportions with all organic solvents. It is chemically closely related to isophorone. Trimethylcyclohexanone dissolves cellulose nitrate, low molecular mass PVC grades, poly(vinyl acetate), vinyl chloride–vinylacetate copolymers, chlorinated rubber, alkyd resins, unsaturated polyester resins, epoxy resins, acrylic resins, etc.

In paints it is used as a leveling agent for air- and oven-drying systems. It counteracts bubble and crater formation and improves flow and gloss. Vinyl paints based on low molecular mass poly(vinyl chloride) or vinyl chloride copolymers that are used to coat metals or plastics, exhibit good storage stability without gelling when trimethylcyclohexanone is added, even with high contents of diluents. Trimethylcyclohexanone is used in combination with suitable diluents as a temporary plasticizer in the processing of poly(vinyl chloride). In pastes consisting of poly(vinyl chloride) and plasticizers it serves as a thinner with a low gelling tendency. Trimethylcyclohexanone is used as a solvent in cellulose nitrate emulsion lacquers for coating leather and as a cosolvent for pesticide formulations. It is a starting material for various syntheses. Oxidation yields peroxides which are used as catalysts for the polymerization of unsaturated compounds with a long pot life. Trimethylcyclohexanone oxime prevents skin formation in air-drying paints. It can be used in the synthesis of polymers such as polyamides, polyesters, or polyurethanes. A substituted cyclic monoamine (3,3,5-trimethylcyclohexylamine) is formed by aminating hydrogenation, which is used as an anticorrosive agent, in cosmetic articles, or for special chemical syntheses.

Isophorone [269], [270] is an unsaturated cyclic ketone. It consists of α-isophorone [*78-59-1*] (3,5,5-trimethyl-2-cyclohexen-1-one), which contains about 1 – 3 % of the isomer β-isophorone [*471-01-2*] (3,5,5-trimethyl-

3-cyclohexen-1-one) (→ Ketones, Chap. 5.4.). Isophorone is a stable, water-white liquid with a mild odor that is miscible in all proportions with organic solvents. It dissolves many natural and synthetic resins and polymers, such as poly(vinyl chloride) and vinyl chloride copolymers, poly-(vinyl acetate), polyacrylates, polymethacrylates, polystyrene, chlorinated rubber, alkyd resins, saturated and unsaturated polyesters, epoxy resins, cellulose nitrate, cellulose ethers and esters, damar resin (dewaxed), kauri, waxes, fats, oils, phenol--, melamine--, and urea–formaldehyde resins, as well as plant protection agents. However, isophorone does not dissolve polyethylene, polypropylene, polyamides, polyurethanes, polyureas, polyacrylonitrile, polycarbonate, cellulose triacetate, or sandarac.

Isophorone is used in the paint industry as a high-boiling solvent for physically- and oven-drying paints. It improves flow, gloss, adhesion, and the wetting of the substrate and pigments.

Isophorone is used as a high-boiling solvent in cellulose nitrate emulsion lacquers for coating leather. In printing inks for plastic substrates that are based on vinyl resins isophorone reduces the viscosity at high solids contents, it also improves the adhesion due to its swelling ability for poly(vinyl chloride) and other plastics. In the formulation of plant protection agents isophorone is used as a solvent having a high dilutability, good emulsifiability, and good emulsion stability. It is employed in adhesives on account of its universal solvency for many thermoplastic polymers. Isophorone is used in admixture with low-boiling compounds particularly for bonding articles made of poly(vinyl chloride) or polystyrene. The special chemical structure of isophorone with its keto group and an olefinic double bond means that isophorone can be used for the synthesis of a large number of compounds and products including solvents, plasticizers, glycols, amines, diamines, diisocyanates, and dicarboxylic acids.

9.8. Esters

See also → Esters, Organic.

Esters are clear liquids that often have a pleasant, fruity odor. They are neutral and very stable, but can be hydrolyzed on heating in the presence of strong acids or bases. They are less polar than the corresponding alcohols. Esters have an extremely good solvency for polar substances; with increasing carbon chain length in the alcohol and acid groups the solvency for polar products decreases, but increases for less polar products. Lower esters are partially water-soluble. The acetates are the most important ester solvents for the paint industry (DIN 53 246). Formates are used less because they have a more powerful physiology and are more readily hydrolyzed. Propionates, butyrates, and isobutyrates are of minor importance on account of their intense fruity odor. Certain esters of glycolic and lactic acids, as well as dimethyl esters of dicarboxylic acid mixtures are also important.

Methyl formate [*107-31-3*] is a colorless, water-soluble liquid. It dissolves cellulose nitrate, cellulose acetate, oils, and fatty acids.

Ethyl formate [*109-94-4*] is partially miscible with water. It dissolves cellulose nitrate, cellulose acetate, and many resins.

Butyl formate [*592-84-7*] is slightly soluble in water. It dissolves cellulose nitrate, fats, oils, many polymers, and chlorinated rubber. It does not, however, dissolve cellulose acetate.

Isobutyl formate [*542-55-2*] has dissolution properties similar to those of butyl formate. It is a constituent of commercially available mixed solvents for paints.

Methyl acetate [*79-20-9*] is partially miscible with water and readily miscible with most organic solvents. It has a good solvency for cellulose esters and ethers, colophony, urea--, melamine--, and phenol–formaldehyde resins, poly(vinyl acetate), alkyd resins, ketone resins, and other resins. It does not dissolve shellac, damar resin, copal, or poly(vinyl chloride). Methyl acetate is used as a highly volatile solvent by itself or mixed with alcohols or other esters to reduce the viscosity of paints, as a substitute for acetone for adhesives, and as a softening agent for stiff shoe caps in the shoe industry.

Ethyl acetate [*79-20-9*] is a colorless, neutral liquid that is partially miscible with water and has a pleasant, fruity odor. It has a good solvency for cellulose nitrate, cellulose ethers, chlorinated rubber, poly(vinyl acetate), vinyl chloride copolymers, polyacrylates, polystyrene, fats, oils, and many natural and synthetic resins (alkyd resins, saturated polyesters,

ketone resins). Cellulose acetate is, however, dissolved only in the presence of small amounts of ethanol. Poly(vinyl chloride) is insoluble.

Ethyl acetate is one of the most important solvents for quick-drying paints (e.g., wood paints based on cellulose nitrate). It is also commonly employed in isocyanate paints. It increases the dilutability with non-solvents and diluents. Ethyl acetate is also used in adhesives, leather lacquers, leather impregnating agents, as an extracting and cleansing agent, as a fragrance in the perfume industry, in polishes, in the production of glazed paper and transparent paper, and in organic syntheses.

Propyl acetate [*109-60-4*] and *isopropyl acetate* [*108-21-4*] [271] are only slightly soluble in water. They are less volatile than ethyl acetate and have an improved solubility for less polar resins. Cellulose acetate is insoluble.

Butyl acetate [*123-86-4*] is a colorless, neutral, water-immiscible liquid with a pleasant, fruity odor. It has a good solvency for cellulose nitrate, cellulose ethers, chlorinated rubber, postchlorinated poly(vinyl chloride), poly(vinyl acetate), polyacrylates, polymethacrylates, vinyl chloride copolymers, polystyrene, natural and synthetic resins, alkyd resins, fats, and oils. Cellulose acetate is insoluble.

Butyl acetate is the most important moderately volatile solvent for the paint industry. Its volatility is sufficiently high for it to evaporate rapidly from the paint film, but is low enough to prevent cratering, blushing, and flow disorders. The solvency of butyl acetate is increased considerably by adding butanol. Butyl acetate is generally used together with aromatic hydrocarbons in paint formulations. The product has a low intrinsic viscosity and is therefore suitable as an auxiliary solvent in high-solids paints; it is also the most widely used solvent in polyurethane paints.

Isobutyl acetate [*110-19-0*] is a colorless, neutral liquid with a pleasant, fruity odor. It is miscible with organic solvents, but immiscible with water. Isobutyl acetate has a high solvency for cellulose nitrate, colophony, damar resin, ketone and ketone–formaldehyde resins, maleate resins, urea and melamine resins, and phenolic and alkyd resins. Polymers such as polystyrene, poly(vinyl ethers), poly(vinyl acetate), polyacrylates, chlorinated rubber and vinyl chloride copolymers, as well as fats, greases, and oils are readily dissolved. Postchlorinated poly(vinyl chloride) is less soluble. Polyisobutene, cellulose ethers, polymethacrylates, poly(vinyl butyrals), natural rubber, and manila copal are swollen. Shellac, cellulose acetate, cellulose acetobutyrate, poly(vinyl chloride), and poly(vinyl formal) are insoluble.

Isobutyl acetate has a higher volatility and lower flash point than butyl acetate, and is therefore used in the production of quick-drying cellulose nitrate lacquers. On account of its low water content it can be used as a solvent and diluent for polyurethane paints. Isobutyl acetate is used as a viscosity-reducing auxiliary solvent in low-solvent paints.

sec-Butyl acetate [*105-46-4*] is comparable to isobutyl acetate, but is highly volatile and less thinnable. It is of only minor importance as a solvent.

Amyl acetate [*628-63-7*] and *isoamyl acetate* [*123-92-2*] are comparable to butyl acetate as regards solvency and dilutability, but are less volatile. They have a rather intense odor and are used in nail polishes.

2-Ethylhexyl acetate [*103-09-3*] is a high-boiling solvent with good solvency properties. It is used in stoving enamels.

Octyl acetate is a high-boiling mixture of isomers that is used in stoving enamels.

Nonyl acetate is a high-boiling mixture of isomers that is used in stoving enamels.

Hexyl acetate [*142-92-7*] has a good solvency for resins, polymers, cellulose derivatives, fats, and oils. Cellulose acetate is insoluble. Small amounts of hexyl acetate are used as a leveling agent in paints.

Cyclohexyl acetate [*622-45-7*] is very slightly miscible with water, but completely miscible with common organic solvents. Its solvency properties are comparable to those of amyl acetate. Cyclohexyl acetate dissolves oils, fats, resins, waxes, cellulose nitrate, cellulose tripropionate and acetobutyrate, alkyd resins, unsaturated and saturated polyester resins, phenolic resins and aminoplasts, poly(vinyl chloride), vinyl chloride copolymers, poly(vinyl acetate), poly(vinyl ethers), epoxy resins, and acrylic resins, basic dyes, blown oils, crude rubber, metallic soaps, shellac, and bitumen.

In metal paints cyclohexyl acetate improves wetting and flow properties and prevents blistering. On account of its low water miscibility

and high surface tension, cyclohexyl acetate promotes the formation of stable emulsions when used as a cosolvent (e.g., in pest control agents and cellulose nitrate emulsion lacquers for coating leather). It is used for the production of pigment pastes on account of its good solvency for basic dyes. It is also employed as a fragrance component in the perfume industry.

Benzyl acetate [*140-11-4*] is an aromatic smelling, water-insoluble liquid. It is used as a high boiler in printing inks.

Methyl glycol acetate [*110-49-6*] (2-methoxyethyl acetate) is a neutral liquid with a mild odor. It is miscible with water and organic solvents and has a good solvency for many natural and synthetic resins. It does not dissolve poly(vinyl chloride), rubber, polyisobutene, poly(vinyl butyrate), shellac, and damar resin. Methyl glycol acetate imparts good flow properties and high dilutability to paints and prevents blistering and blushing. On account of its teratogenic properties it is being replaced by other solvents in paints.

Ethyl glycol acetate [*111-15-9*] (2-ethoxyethyl acetate) is a colorless, neutral liquid that is partially miscible with water and readily miscible with organic solvents. It has a slight odor. Ethyl glycol acetate dissolves many natural and synthetic resins. Cellulose acetate is swollen. Poly(vinyl chloride), rubber, and polyisobutene are insoluble. Its use in paints is restricted on account of its teratogenic properties.

Butyl glycol acetate [*112-07-2*] (2-butoxyethyl acetate) is insoluble in water, but miscible with organic solvents. It is a high boiler that is used to improve flow properties in stoving enamels. It has a good solvency for slightly polar resins and polymers, fats, and oils.

Ethyl diglycol acetate [*111-90-0*] [2-(2-ethoxyethoxy)ethyl acetate] is used as a high boiler to improve the flow properties and prevent blistering in industrial paints, automotive finishes, and coil coating of metals.

Butyl diglycol acetate [*112-17-4*] [2-(2-butoxyethoxy)ethyl acetate] is a high boiler that is used as a temporary plasticizer, as a leveling agent in stoving enamels and in printing inks, as a film-forming auxiliary in acrylate copolymer dispersions, and to reduce the viscosity of poly(vinyl chloride) plastisols.

1-Methoxypropyl acetate [*108-65-6*] and *2-methoxypropyl acetate* are pleasantly smelling liquids that are partially soluble in water, and miscible with organic solvents. Their dissolution properties and evaporation behavior are comparable but not identical to those of ethyl glycol acetate. 1-Methoxypropyl acetate is less toxic than methyl and ethyl glycol acetates; 2-methoxypropyl acetate is teratogenic.

Ethoxypropyl acetate [*54839-24-6*] is an isomeric mixture containing 1-ethoxypropyl acetate as the principal component. It is less toxic than ethyl glycol acetate, with which it shares many physical properties. Ethoxypropyl acetate differs from ethyl glycol acetate however as regards dissolution properties.

3-Methoxybutyl acetate [*4435-53-4*] (butoxyl) is a weakly smelling liquid that is partially soluble in water and miscible with organic solvents. Dissolution properties resemble those of ethyl glycol acetate, but volatility is lower.

Propionate esters are comparable to acetate esters having the same number of carbon atoms as regards dissolution, mixing, and evaporation properties. Propionates have a stronger odor than acetates and are therefore of only limited importance as solvents.

Ethyl 3-ethoxypropionate [*763-69-9*] is a high-boiling solvent that is a less toxic alternative to ethyl glycol acetate, with a comparable property spectrum.

Butyrate esters are comparable to acetate esters with the same number of carbon atoms as regards dissolution, mixing, and evaporation properties, but have a more intense odor, in some cases reminiscent of pineapple or banana. Butyl butyrate [*109-21-7*] is important as a high-boiling solvent.

Isobutyrate esters are comparable to butyrate esters, but have a slightly lower boiling point and higher volatility. Isobutyl isobutyrate [*97-85-8*] has some importance as a high-boiling solvent.

Ethyl lactate [*97-64-3*] is miscible with water and most organic solvents. It is a slowly evaporating solvent with a mild odor. It dissolves cellulose nitrate, cellulose acetobutyrate, strongly polar resins, and polar polymers, [e.g., poly(vinyl acetate) and polyacrylates]. Ethyl lactate has limited solvency for slightly polar resins, polystyrene, poly(vinyl chloride), and vinyl chloride copolymers. It is used as a powerful high-boiling solvent that can be diluted to a high degree with non-solvents.

Butyl lactate [*138-22-7*] has a good solvency for less polar resins and polymers and good dilutability with aliphatic hydrocarbons. It does not dissolve cellulose acetate. Butyl lactate is a high-boiling solvent that is used in small amounts as a leveling agent.

Butyl glycolate [*7397-62-8*] (butyl hydroxyacetate) is comparable to butyl acetate as regards dissolution properties and evaporation behavior. It has a good solvency for fats, oils, alkyd resins, cellulose nitrate, and many resins. It has a high dilutability with alcohols and aromatic hydrocarbons.

Butyl glycolate reduces the viscosity of alkyd resin paints. It improves the flow properties and gloss in air-drying and oven-drying paints, especially in coil coating and leather lacquers. It is also used to lower the film-forming temperature in poly(vinyl acetate) dispersions.

Dimethyl adipate [*627-93-0*], *glutarate* [*1119-40-0*], and *succinate* [*106-65-0*] are used as a high-boiling mixture with good dissolution properties in stoving enamels, coil-coatings, and in the automobile industry.

Ethylene carbonate [*96-49-1*] is soluble in water and organic solvents and solid at room temperature. It is a high boiler that is insoluble in gasoline and turpentine oil. It has a high solvency for polyacrylonitrile, polyamides, glycol terephthalates, and poly(vinyl chloride). Cellulose nitrate and cellulose acetobutyrate only dissolve in the presence of alcohol or esters. Ethylene carbonate is used for polyacrylonitrile spinning solutions.

Propylene carbonate [*108-32-7*] is liquid at room temperature. It is a high boiler with a solvency resembling that of ethylene carbonate. It dissolves polyacrylonitrile only in combination with ethylene carbonate. Propylene carbonate is used in paints as a high-boiling solvent and film-forming auxiliary, especially in poly(vinyl fluoride) and poly(vinylidene fluoride) systems. It is also employed as an auxiliary in the pigment and dye industry.

Butyrolactone [*96-48-0*] has a mild odor with good dissolution properties. It is a high-boiling solvent that is used to improve properties (→ Butyrolactone).

9.9. Ethers

See also → Ethers, Aliphatic.

Straight-chain aliphatic ethers are water-clear, highly mobile liquids with a high volatility and characteristic, anesthetizing odor. On account of their high volatility they are of only minor importance in paint technology. Ethers are usually used as extracting agents in chemical syntheses and for isolating natural substances. They are highly flammable and form explosive peroxides in the presence of oxygen, especially on exposure to light.

Cycloaliphatic ethers are better solvents for binders and are therefore more important in paint technology.

Ethylene and propylene glycol ethers are extremely good solvents (DIN 55 999). For toxicity reasons monoethylene glycol ethers are being replaced in the paint, dye, and printing ink industries by other solvents, including the corresponding monopropylene glycol ethers.

Diethyl ether [*60-29-7*] (DEE, ethoxyethane, ether) is a clear, colorless, highly mobile liquid with a low boiling point and a characteristic pleasant odor. It is miscible in all proportions with common organic solvents such as alcohols, ketones, hydrocarbons, esters, and ethereal oils. Diethyl ether has an evaporation number of 1.

Diethyl ether is widely used in the chemical industry as a solvent, extracting agent, and reaction medium on account of its chemical resistance in acid and alkaline media, its low boiling point, and favorable dissolution properties (e.g., for organometallic compounds). Diethyl ether mixed with ethanol is an excellent solvent for cellulose nitrate. It is used in large amounts in the gelatinization of cellulose nitrate and preparation of collodion solution. Ether is employed in medicine as an anesthetic, but this use is declining.

Diisopropyl ether [*108-20-3*] is miscible with most organic solvents, but immiscible with ethylene glycol and glycerol. It is only slightly water soluble. Diisopropyl ether is an excellent solvent for natural oils, mineral oils, and waxes. It is used as an extracting agent and reaction medium in chemical and pharmaceutical syntheses.

Dibutyl ether [*142-96-1*] and *di-sec-butyl ether* [*6863-58-7*] are very slightly soluble in water but miscible with organic solvents ex-

cept ethylene glycol and glycerol. They are used as extracting agents and reaction media in the chemical and pharmaceutical industries.

Methyl tert-butyl ether [*1634-04-4*] (MTB) is a combustible, clear, colorless liquid with a low viscosity and characteristic, turpentine-like odor (→ Methyl Tert-Butyl Ether). It is miscible with organic solvents, and is only slightly soluble in water. It forms azeotropic mixtures with some solvents such as methanol. MTB does not undergo autoxidation and, in contrast to other ethers, it does not form peroxides with atmospheric oxygen. It improves the antiknock properties when added to motor gasoline.

Tetrahydrofuran [*109-99-9*] (oxolane, tetramethylene oxide, oxacyclopentane, THF) [272] is a colorless, highly volatile liquid having an outstanding solvency (→ Tetrahydrofuran). Under prolonged exposure to air it tends to form peroxides. Tetrahydrofuran is completely miscible with most organic solvents and water. It forms azeotropic mixtures with a number of solvents. Tetrahydrofuran dissolves practically all plastics apart from certain polyamides (e.g., polyamide 6 and 12) and polytetrafluoroethylene.

Tetrahydrofuran is used alone or mixed with other solvents to prepare poly(vinyl chloride) and polyurethane solutions for coating films, sheets, and textiles (leather imitates). The special surface properties of video, computer, and recording tapes are obtained by using appropriate coatings that are prepared from tetrahydrofuran- containing solutions. Offset printing plates are produced by coating them with light-sensitive compounds that are applied from tetrahydrofuran- containing solutions. Tetrahydrofuran is also highly suitable as a solvent for printing inks based on poly(vinyl chloride). Its outstanding solvency for many plastics makes tetrahydrofuran a particularly suitable solvent for a number of special finishes that are used to coat plastics. Tetrahydrofuran has proved to be especially useful in cold cleansers for eliminating impurities and contaminants that can otherwise only be removed with difficulty.

Tetrahydrofuran is extremely suitable for extracting active agents from natural or synthetic raw materials. Substances can be separated on the basis of the specific solvency properties of tetrahydrofuran [e.g., insoluble polyamides and soluble poly(vinyl chloride)]. On account of its good dissolution properties for poly(vinyl chloride) tetrahydrofuran can be used alone or with other solvents to bond PVC pipes and for solution welding of PVC sealant films. Solutions of PVC in tetrahydrofuran are employed for gap-filling bonding of PVC moldings. Tetrahydrofuran is used as a stripper to remove coats of paint. It also serves as a reaction medium in the preparation of chemical intermediates with organometallic compounds.

1,4-Dioxane [*123-91-1*] has a slight odor reminiscent of butanol, and is miscible with water and organic solvents (→ Dioxane). It is a good solvent for cellulose derivatives, polymers, chlorinated rubber, and resins [273].

Metadioxane [*505-22-6*] (2,2-dimethyl-4-hydroxymethyl-1,3-dioxolane) is a high-boiling solvent with an excellent solvency for resins and polymers. It is used in printing inks, adhesives, and in the textile sector.

9.10. Glycol Ethers

Methyl glycol [*109-86-4*] (2-methoxyethanol, ethylene glycol monomethyl ether) has a slight odor, and is miscible with water and organic solvents except aliphatic hydrocarbons. It is a very good solvent for many natural and synthetic resins. It does not dissolve fats, oils (except castor oil), damar resin, rubber, bitumen, hydrocarbon resins, polystyrene, poly(vinyl chloride), and vinyl chloride copolymers. On account of its teratogenic properties it is being replaced as a solvent in the paint and colorants sector by other solvents or solvent mixtures.

Ethyl glycol [*110-80-5*] (2-ethoxyethanol, ethylene glycol monoethyl ether) is a neutral, colorless liquid with a slight odor, and is miscible in all proportions with water and organic solvents. Ethyl glycol has a high solvency for many natural and synthetic resins and binders. Damar resin, rubber, bitumen, cellulose acetate, polystyrene, and poly(vinyl chloride) are insoluble. Its use as a solvent in the paint and colorants industry is restricted on account of its teratogenic properties.

Propyl glycol [*2807-30-9*] (2-propoxyethanol, ethylene glycol monopropyl ether) and *isopropyl glycol* [*109-59-1*] (2-isopropoxyeth-

anol, ethylene glycol monoisopropyl ether) correspond to ethyl glycol as regards dissolution and miscibility properties, but evaporate more slowly and have a better solvency for slightly polar resins. They are less toxic than ethyl glycol and are therefore increasingly used as alternatives.

Butyl glycol [*111-76-2*] (2-butoxyethanol, ethylene glycol monobutyl ether) is a neutral, colorless liquid with a very weak, pleasant odor. It is miscible with water at room temperature, but has a miscibility gap with water at higher temperatures. It is miscible with organic solvents, and a very good solvent for cellulose nitrate, cellulose ethers, colophony, shellac, chlorinated rubber, polyacrylates, polymethacrylates, alkyd resins, phenol --, area --, and melamine – formaldehyde resins, oils, fats, and synthetic resins. Damar resin, rubber, bitumen, polystyrene, and poly(vinyl chloride) are insoluble. Poly(vinyl acetate), poly(vinyl butyral), postchlorinated poly(vinyl chloride), and cellulose acetate are sparingly soluble or swellable. Butyl glycol is widely used in solvent- containing paint systems to improve the flow and surface quality of coatings. It is increasingly used in water-thinnable paints on account of its solubilizing action.

Methyl diglycol [*111-77-3*] [2-(2-methoxyethoxy)ethanol, diethylene glycol monomethyl ether] is miscible with water and most organic solvents. It is a good solvent for cellulose nitrate, colophony, phenol --, urea --, and melamine–formaldehyde resins, alkyd resins, alcohol-soluble maleate resins, ketone – formaldehyde resins, poly(vinyl butyral), poly(vinyl acetate), poly-(vinyl ethers), epoxy resins, castor oil, linseed oil, and turpentine oil. However, it does not dissolve damar resin, rubber, bitumen, polyisobutylene, polystyrene, waxes, mineral oil, polyacrylates, and polymethacrylates. Small amounts are used as a low-volatility solvent in paints to improve the gloss and flow, in the printing ink industry, and for ballpoint pen pastes.

Ethyl diglycol [*111-90-0*] [2-(2-ethoxyethoxy)ethanol, diethylene glycol monoethyl ether] is a neutral, colorless, practically odorless liquid. It is miscible in all proportions with alcohols, esters, ethers, ketones, and water. It is partially miscible with aromatic and aliphatic hydrocarbons. Ethyl diglycol dissolves many paint resins, such as cellulose nitrate, chlorinated rubber, shellac, colophony, phenolic resins, urea– and melamine – formaldehyde resins, polyacrylates, esters, poly(vinyl acetate), as well as alkyd, ketone, and maleate resins. However, it does not dissolve cellulose acetate, poly(vinyl chloride), vinyl chloride copolymers, polystyrene, polymethacrylates, asphalt, and rubber. On account of its low solidification point and low viscosity at low temperatures, ethyl diglycol is a constituent of many brake fluids. It is used in the paint industry to improve gloss and flow properties, and thereby increase the dilutability. Ethyl diglycol can be used to predissolve alcohol-soluble dyes and is a constituent of many wood stains. This solvent is also used in printing inks and as a cleaning agent in offset printing. It is a constituent of Indian inks and ballpoint pen pastes. Ethyl diglycol phthalate is an excellent plasticizer for vinyl resins. Ethyl diglycol is used as a solvent in the printing and dyeing of textile fibers and fabrics. It also acts as a solubilizer for detergent raw materials in aqueous solutions and in drilling and cutting fluids. In the determination of the saponification value of waxes, resins, and fats, ethyl diglycol has the advantage that it can substantially accelerate saponification because it is a high-boiling solvent.

Butyl diglycol [*112-34-5*] [2-(2-butoxyethoxy)ethanol, diethylene glycol monobutyl ether] is a clear, colorless, neutral liquid with a pleasantly mild odor. It is miscible with water and organic solvents, including aliphatic compounds. Butyl diglycol has a high solvency for cellulose nitrate, cellulose ethers, chlorinated rubber, poly(vinyl acetate), polyacrylates, and some oils, as well as for many synthetic resins, natural resins, and dyes. Polystyrene, poly(vinyl chloride), fats, and most oils are not dissolved.

Butyl diglycol is used as a high-boiling solvent to improve gloss and flow properties. On account of its high evaporation number even additions of $< 5\,\%$ considerably improve paint properties, without noticeably increasing the stoving time. In cellulose nitrate and cellulose ether lacquers even smaller amounts are effective. In emulsion paints and cold-hardening paints butyl diglycol improves the coatability and enhances the surface gloss. On account of its good solvency for resins and dyes, butyl diglycol is used with other low-volatility solvents for coatings

and printing inks. It is used as a solubilizer in mineral oil products.

Ethyl triglycol [*112-50-5*] [2-[2-(ethoxyethoxy) ethoxy]ethanol, triethylene glycol monoethyl ether] is an almost colorless, neutral, mild-smelling liquid with a low hygroscopicity. It is soluble in water and most organic solvents, but is only partially miscible with aromatic and aliphatic hydrocarbons. Ethyl triglycol dissolves cellulose nitrate, shellac, colophony, ketone resins, maleate resins, chlorinated rubber, alkyd resins, and many other paint resins. It does not dissolve cellulose acetate, poly(vinyl chloride), vinyl chloride copolymers, fats, oils, and rubber.

The uses of ethyl triglycol are similar to those of ethyl diglycol. It serves as a solubilizer for incompatible liquids in the production of insecticides, and in the detergent industry in handwash pastes. It is employed in printing inks and, in small amounts, in wood paints to prevent the wood fibers from standing perpendicular of the surface during painting. Ethyl triglycol is used in hydraulic and brake fluids because its viscosity remains largely constant under temperature fluctuations. It is also used as an intermediate in the production of plasticizers.

Butyl triglycol [*143-22-6*] [2-[2-(butoxyethoxy)ethoxy]ethanol, triethylene glycol monobutyl ether] is an almost colorless, neutral, weakly smelling liquid. It is soluble in water and most organic solvents, but is only partially miscible with aromatic and aliphatic solvents. Its dissolution properties are comparable to those of butyl diglycol. Butyl triglycol dissolves cellulose nitrate, cellulose ethers, chlorinated rubber, poly(vinyl acetate), colophony, many other natural and synthetic resins, as well as drying greases and oils. Bitumen, nondrying fats and oils, cellulose acetate, poly(vinyl chloride), and rubber are, however, insoluble. Butyl triglycol serves as a solubilizer for mutually incompatible liquids, and is used in the production of household and metal cleansing agents as well as for wood preservation. It is employed in cutting and hydraulic oils. Butyl triglycol is used in the production of Indian inks, writing inks, and ballpoint pen pastes. In the paint industry it is suitable as a high-boiling solvent in stoving enamels, as a leveling agent, and as an additional solvent in wood paints, in order to prevent wood fibers standing proud from the surface. Butyl triglycol is a useful solvent for the formulation of pharmaceutical and cosmetic preparations and in the leather auxiliaries industry.

Butyl tetraglycol [2-[2-(butoxyethoxyethoxy)-ethoxy]ethanol, tetraethylene glycol monobutyl ether] is a neutral, practically odorless liquid that is soluble in water and most organic solvents, but only partially miscible with aromatic and aliphatic solvents. Its properties are comparable to those of butyl diglycol. Butyl tetraglycol dissolves cellulose nitrate, cellulose ethers, chlorinated rubber, poly(vinyl acetate), colophony, and many other natural and synthetic resins. However, it does not dissolve nondrying fats and oils, cellulose acetate, poly(vinyl chloride), and rubber. Butyl tetraglycol is used as a solubilizer on account of its good solvency for organic solvents, water, and natural and synthetic resins. It is also a constituent of hydraulic and brake fluids.

Diethylene glycol dimethyl ether [*111-96-6*] is a hygroscopic, weakly smelling liquid that is miscible with water and organic solvents. It dissolves vinyl chloride copolymers, postchlorinated poly (vinyl chloride), polymethacrylate, polystyrene, polychloroprene, and cellulose acetate. It does not dissolve rubber and polyethylene, and swells poly(vinyl chloride). Diglycol dimethyl ether also dissolves sodium borohydride, other covalent inorganic metal compounds, and sodium. It is used as a solvent in chemical reactions involving metals and organometallic compounds.

Methoxypropanol [*107-98-2*] (1-methoxy-2-propanol). Commercially available methoxypropanol also contains small amounts of 2-methoxy-1-propanol. It is a colorless, neutral liquid with a weak pleasant odor that is miscible in all proportions with water and organic solvents. The properties of methoxypropanol are largely comparable to those of ethyl glycol [274]. It has a somewhat higher volatility and, as a solvent component in paints and printing inks, improves the wetting of some pigments and colorants. It has a good solvency for cellulose nitrate, cellulose ethers, chlorinated rubber, poly(vinyl acetate), poly(vinyl butyral), ketone and ketone–formaldehyde resins, shellac, colophony, phenol--, melamine--, and urea–formaldehyde resins, alkyd resins, polyacrylates, polymethacrylates, castor oil, linseed oil,

and some vinyl chloride copolymers. However, it does not dissolve copal resins, rubber, bitumen, cellulose acetate, polystyrene, poly(vinyl alcohol), and poly(vinyl chloride). On account of its mild, pleasant odor, methoxypropanol is extremely suitable for cellulose nitrate lacquers used to coat wood, paper, and metals. Being a moderately volatile solvent, it improves paint penetration, flow properties, and the gloss of paint coats; it also prevents blushing and formation of fish eyes and blisters. Addition of methoxypropanol does not delay the drying of paint systems. It increases the dilutability with inexpensive non-solvents, reduces and stabilizes the paint viscosity, and improves the coatability of paints. Methoxypropanol only slowly swells dry paint coats, so that it facilitates painting over previous coats. It is used as a solvent in printing inks (flexographic, gravure packaging printing) to improve their gloss and flow. On account of its good dissolution properties for dyes and ability to wet pigments, it intensifies the color of the inks.

Ethoxypropanol is a mixture of 1-ethoxy-2-propanol [*1569-02-4*] and 2-ethoxy-1-propanol. Its physical properties are very similar to those of ethyl glycol, but is a less toxic alternative.

Isopropoxypropanol consists of a mixture of 1-isopropoxy-2-propanol [*3944-36-3*] and 2-isopropoxy-1-propanol [*3944-37-4*]. It is a weakly smelling liquid with a relatively high boiling that is miscible with water and organic solvents. Its dissolution properties, evaporation properties, and uses are similar to those of butyl glycol. It is an effective solubilizer and used as an auxiliary solvent in high-solids and waterborne paints.

Isobutoxypropanol is a mixture of 1-isobutoxy-2-propanol [*26447-43-8*] and 2-isobutoxy-1-propanol. It is a weakly smelling liquid with a high boiling point that is miscible with water and organic solvents. Its dissolution properties, evaporation properties, and uses are similar to those of butyl glycol. Isobutoxypropanol is a highly effective solubilizer and is used as an auxiliary solvent in high-solids and waterborne paints. Propylene glycol *tert*-butyl ether is similar to isobutoxypropanol [275].

Methyl dipropylene glycol [*34590-94-8*] [2-(2-methoxypropoxy)propanol, dipropylene glycol methyl ether] (isomer mixture) is a high-boiling solvent. It is waterclear and miscible in all proportions with water, and has only a slight intrinsic odor. It readily dissolves cellulose nitrate, cellulose esters and ethers, as well as many natural and synthetic resins. On account of its slow evaporation rate small amounts of methyl dipropylene glycol are added to paints to control their flow properties, evaporation rate, and dilutability with non-solvents. It improves the coatability of cellulose nitrate lacquers, chlorinated rubber paints, and alkyd resin paints. Methyl dipropylene glycol is also suitable as a film-forming auxiliary in dispersions and as an auxiliary solvent in waterborne paints. It is highly effective as a solubilizer in cleansing agents and as a solvent in writing inks, pastes, and printing inks.

Methoxybutanol [*30677-36-2*] (3-methoxy-1-butanol) is a mild-smelling liquid that is miscible with water and organic solvents. It has a good solvency for cellulose nitrate, cellulose esters, poly(vinyl butyral), ketone resins, phenol --, urea --, and melamine – formaldehyde resins, alkyd and maleate resins, plasticizers, fats, and drying oils. However, it does not dissolve mineral oils, waxes, rubber, chlorinated rubber, cellulose acetate, polyisobutene, polystyrene, poly(vinyl chloride), and vinyl chloride copolymers. It is used like butanol as a slow-evaporating solvent.

9.11. Miscellaneous Solvents [276]

Methylal [*109-87-5*] (formaldehyde dimethyl acetal, dimethoxymethane) is a pleasantly smelling, extremely volatile solvent. It dissolves polystyrene, poly(vinyl acetate), vinyl chloride copolymers, acrylates, methacrylates, and synthetic and natural resins. It is used in paints and lacquers, adhesives, and aerosols. Also it is an important extracting agent for natural substances, essences, and oils. It serves as a reaction medium in the chemical industry and as an intermediate for chemical syntheses.

Dimethylacetal [*534-15-6*] (acetaldehyde dimethyl acetal, 1,1-dimethoxyethane) is a neutral liquid that is miscible with water and organic solvents. It dissolves cellulose nitrate, cellulose ethers, poly(vinyl acetate), polyacrylates, polymethacrylates, poly(vinyl ethers), some vinyl chloride copolymers, and synthetic and

natural resins. It does not dissolve poly(vinyl chloride), polystyrene, chlorinated rubber, or cellulose acetate. It is used in the production of paints, adhesives, and shoe- cap stiffeners.

N,N-Dimethylformamide [*68-12-2*] (DMF) [277] is miscible with water and organic solvents except aliphatic hydrocarbons (→ Formamides). It is a good high-boiling solvent for cellulose esters, cellulose ethers, poly(vinyl chloride), vinyl chloride copolymers, poly(vinyl acetate), polyacrylonitrile, polystyrene, chlorinated rubber, polyacrylates, ketone resins, and phenolic resins. Alkyd resins and resin esters are partially soluble. Dimethylformamide does not dissolve polyethylene, polypropylene, urea–formaldehyde resins, rubber, or polyamides. It is used as a solvent in printing inks, for polyacrylonitrile spinning solutions [278], and as a solvent in the synthesis of acetylene.

N,N-Dimethylacetamide [*127-19-5*] (DMA) is miscible with water and organic solvents. It has a very good solvency for many resins and polymers. It is used in the production of acrylic fibers, films, sheets, and coatings, and as a reaction medium and intermediate in organic syntheses.

Dimethyl sulfoxide [*67-68-5*] (DMSO) is a clear, colorless liquid that is miscible with water and organic solvents except aliphatic hydrocarbons (→ Sulfones and Sulfoxides). It is a good high-boiling solvent for cellulose esters, cellulose ethers, poly(vinyl acetate), polyacrylates, vinyl chloride copolymers, polyacrylonitrile, chlorinated rubber, and many resins. It is used in polyacrylonitrile spinning solutions, in paint-removal agents, as a film-forming auxiliary in dispersions, as an extracting agent, and as a reaction medium in organic syntheses [279], [280].

Tetramethylene sulfone [*126-33-0*] (sulfolane) is a waterclear liquid that is miscible with water and most organic solvents except aliphatic hydrocarbons. It dissolves cellulose acetate, cellulose nitrate, cellulose ethers, poly(vinyl chloride), vinyl chloride copolymers, poly(vinyl acetate), polystyrene, and many resins. Its solvency is lower than that of dimethyl sulfoxide. Tetramethylene sulfone is of only minor importance as a solvent.

Carbon disulfide [*75-15-0*] is a clear, highly mobile liquid that is highly refractive and very flammable (→ Carbon Disulfide). It is insoluble in water, but generally miscible with organic solvents. It has a good solvency for fats, oils, waxes, rubber, and many resins. Cellulose esters are insoluble, vinyl polymers dissolve only in mixtures with ketones or esters. Carbon disulfide is used in the production of silk, rubber solutions, and poly(vinyl chloride) spinning solutions. It is of no importance for paints, plastics solutions, or as a fat-extracting agent.

2-Nitropropane [*79-46-9*] is a colorless, nonhygroscopic liquid with a mild odor (→ Nitro Compounds, Aliphatic, Chap. 6.4.). It dissolves cellulose nitrate, cellulose ethers, alkyd resins, chlorinated rubber, poly(vinyl acetate), vinyl chloride copolymers. Poly(vinyl chloride), colophony, polyacrylonitrile, waxes, rubber, and shellac are insoluble. It is used as a cosolvent in paints to improve pigment wetting, flow properties, and electrostatic processing; it also reduces the paint drying time. 2-Nitropropane is classified as carcinogenic.

N-Methylpyrrolidone [*872-50-4*] (NMP) has a fairly mild, amine-like odor, and is miscible with water and most organic solvents (→ 2-Pyrrolidone, Chap. 3.). It has a good solvency for cellulose ethers, butadiene – acrylonitrile copolymers, polyamides, polyacrylonitrile, waxes, polyacrylates, vinyl chloride copolymers, and epoxy resins. It is used in paint removers and stripping paints to reduce paint viscosity, and to improve the wettability of paint systems. *N*-Methylpyrrolidone is also employed for the extraction of hydrocarbons, and as a solvent in the synthesis of acetylene.

Hexamethylphosphoric triamide [*680-31-9*] [281] is a basic, highly polar, nonflammable solvent with a very good solvency. Its dissolution properties are comparable to those of dimethyl sulfoxide and dimethylformamide. It is used for selective dissolution of organic compounds, as a reaction medium in chemical syntheses, as an antifreeze, and as an antistatic agent.

1,3-Dimethyl-2-imidazolidinone [*80-73-9*] (DMI) is a colorless, high-boiling, highly polar aprotic solvent of low toxicity with good chemical and thermal stability. It is miscible with water and most organic solvents. It is used as a reaction medium in preparative organic chemistry, in the production of polyamides, as a solvent in the production of dyes, agrochemicals, and pharmaceuticals and in the electronics industry.

It is also a constituent of nail-polish, ballpoint pen pastes, and coating compositions.

1. Introduction

The *trans,trans* isomer of 2,4-hexadienoic acid is known as sorbic acid [*110-44-1*].

The name is derived from the scientific name of the mountain ash, *Sorbus aucuparia* Linnaeus. In 1859 Hofmann obtained an oil with a characteristic odor from the juice of unripe rowan berries by distillation. He named the most important component of this oil parasorbic acid. Parasorbic acid [*10048-32-5*] is the δ-lactone of sorbic acid. Strong acids or alkalis convert it into the isomeric sorbic acid [3]. The parasorbic acid content of unripe rowan berries is ca. 0.1 % [4].

Sorbic acid occurs in the form of 2-sorboyl-1,3-dimyristin [*7175-63-5*] in the fatty deposits of certain aphids [5].

Doebner established the structure of sorbic acid in 1890 [6], and in 1900 also described the first total synthesis [7].

In 1939/40 Müller [8] in Germany and Gooding in the United States [9] independently discovered the antimicrobial activity of sorbic acid. Industrial supplies of sorbic acid and potassium sorbate became available during the 1950s, first in the United States, shortly thereafter in Germany, and later in Japan. This opened the way to a broad range of applications in the preservation of food, animal feeds, pharmaceuticals, cosmetics, and other non-food applications. Because it is harmless from a physiological standpoint and exhibits favorable sensory characteristics sorbic acid has in the meantime become the leading preservative for foods.

2. Physical Properties

Sorbic acid crystallizes in needles or plates with a weak characteristic odor and a slightly acidic taste; *mp* 132 – 135 °C; *bp* 228 °C (decomp.); n_D^{20} 1.4248, density 1.204. Sorbic acid is soluble in 100 mL of water to the extent of 0.16 g at 20 °C, 0.58 g at 50 °C, and 3.9 g at 100 °C. The solubility in anhydrous lower molecular mass alcohols and anhydrous acetic acid is ca. 11 – 12 g per 100 mL. Liquid fats dissolve 0.5 – 1 g of sorbic acid per 100 mL.

Sorbic acid begins to sublime above 60 °C. The vapor pressure at 20 °C is <0.001 kPa; at 100 °C it is 0.25 kPa, and at 120 °C 1.3 kPa. Sorbic acid is volatile in steam without decomposition. This property is important for its isolation from foods for analytical purposes.

The dissociation constant of sorbic acid is 1.73×10^{-5} at 25 °C, and the pK_a is 4.76. Its pH-dependent dissociation behavior is important in the use of sorbic acid as a preservative. Only the undissociated form has antimicrobial activity.

3. Chemical Properties and Derivatives

The chemical behavior of sorbic acid is determined by the carboxyl group and the conjugated double-bond system. Reactions at the carboxyl group correspond to those of other carboxylic acids; salts, esters, and other acid derivatives are easily prepared by the usual methods. The carboxyl group can be reduced selectively with lithium aluminum hydride to give sorbyl alcohol, 2,4-hexadien-1-ol [*17102-64-6*] [10]. Unlike sorbic acid itself, the alkali salts are readily water soluble, and they are used preferentially for the preservation of systems containing water.

Potassium sorbate [*24634-61-5*], prepared by dissolving sorbic acid in aqueous potassium hydroxide, is of great practical importance. It is sold commercially as a white powder and in granulated form. The stability of potassium sorbate is strongly dependent on its water content, which must be kept well below 0.5 %. At room temperature ca. 140 g potassium sorbate can be dissolved in 100 mL of water. Saturated potassium sorbate solutions contain ca. 58 wt % potassium sorbate.

Calcium sorbate [*7492-55-9*], with a very low water solubility, can be produced by the reaction of sorbic acid with calcium hydroxide in water. Because of its particularly high resistance to oxidation, calcium sorbate is suitable for the production of packaging materials with a preserving effect [11].

The *lower alkyl esters* of sorbic acid also exhibit antimicrobial properties [12]. Unlike sorbic acid, these are also active in neutral and weakly alkaline media. In contrast to sorbic acid and its salts, the sorbate esters have a pronounced odor. The esters of sorbic acid with long chain fatty acids are described as suitable for bread preservation because, in contrast to normal sorbic acid they do not inhibit the growth of the bakery yeasts. However, nowadays a special type of sorbic acid has been developed that can also be used for this purpose.

Reactions of sorbic acid involving the double-bond system are often complex, frequently resulting in mixtures of products. This is due to the differing reactivities of the two double bonds and to side reactions and such subsequent transformations as isomerizations, rearrangements, double-bond migration, and polymerization.

In the case of addition reactions and partial hydrogenation, preferential attack is usually observed at the 4,5 double bond. Even with long reaction times chlorine addition is incomplete, leading to mixtures of various chlorohexenoic acids with an average chlorine content of 38 – 48 wt %. Addition of bromide in the presence of organic solvents leads to 2,3,4,5-tetrabromohexanoic acid [*62284-99-5*]. The major product of partial bromination in aqueous medium is 4,5-dibromo-2-hexenoic acid [*19147-46-7*] [13].

Pure crystalline sorbic acid is surprisingly resistant to air oxidation given that it is doubly unsaturated. At room temperature it remains unchanged for years, although its stability in the solid state depends very much on purity. The shelf life is reduced considerably by traces of solvents, heavy metals, or isomeric hexadienoic acids, which can form as side products during sorbic acid synthesis. The same applies to potassium sorbate. Sodium sorbate [*7757-81-5*] is unstable in the solid state and is therefore not produced industrially. In air, but not in solution, sodium sorbate is converted very rapidly into the sodium salt of 4,5-epoxy-2-hexenoic acid [14]. The oxidation of aqueous solutions of sorbates or solutions of sorbic acid in organic solvents gives rise to a large number of carbonyl compounds, although this reaction depends upon the presence of a large quantity of oxygen is strongly increased by exposure to sunlight [15], [16]. In solutions, the presence of oxygen causes oxidative degradation which may result in brown discoloration [83]. Oxygen-free solutions of sorbic acid remain unchanged even upon exposure to daylight [17]. In intermediate-moisture foods slow degradation of sorbic acid becomes apparent after storage for several months in the presence of air [18]. Potassium dichromate oxidation of acidic, aqueous sorbic acid solutions leads to reproducible yields of malonaldehyde [*542-78-9*]. The analytical determination of sorbic acid acid is based on a color reaction of malonaldehyde with 2-thiobarbituric acid (see Chap. 7).

Sorbic acid that has been incorporated into foods is at least as stable as the important constituents of the foods themselves (e.g., vitamins, flavors, and aromatic substances). The theoreti-

cal potential for sorbic acid to undergo autoxidation thus poses no problems in practice with respect to the preservation of foods.

4. Production

The first described synthesis of sorbic acid consisted of a condensation of *trans*-2-butenal [*123-73-9*] with malonic acid [*141-82-2*] in pyridine [19]. It is named Doebner synthesis after its inventor. Many other syntheses are based on similar principles [94–100]. Most are of no commercial interest because of low yields, expensive starting materials, or high production cost. This also applies, for example, to a process practiced temporarily on an industrial scale in the 1950s and 1960s in the United States by Union Carbide, which involved the oxidation of 2,4-hexadienal [*142-83-6*] to sorbic acid in the presence of catalysts [20–22]. This process was abandoned largely because it gave up to 20 % of the isomeric hexadienoic acids as well, which are much less stable to storage than sorbic acid and could be removed only through an expensive purification process. 2,4-Hexadienal can also be oxidized to sorbic acid by microorganisms [23], [101].

An alternative preparation of sorbic acid involves isomerization of 2,5-hexadienoic acid [*38867-16-2*] by boiling with aqueous alkali. 2,5-Hexadienoic acid is in turn available by treatment of allyl chloride [*107-05-1*] with acetylene [*74-86-2*], carbon monoxide, and water in the presence of tetracarbonylnickel as catalyst [24–26]. The acidic cleavage of 5-vinyl-γ-butyrolactone [*21963-38-2*], obtained from 1,3-butadiene [*106-99-0*] and acetic acid in the presence of redox catalysts, is of no industrial importance [27–31]. Production of sorbic acid by the addition of carbon dioxide to 1,3-pentadiene [*2004-70-8*] in the presence of nickel complexes has also been described [32].

Another common process starts with ketene [*463-51-4*] and 2-butenal [*123-73-9*] [33]. In the presence of salts of divalent transition metals as catalysts, ketene and 2-butenal react at 20 – 80 °C to give a polymeric ester of 3-hydroxy-4-hexenoic acid [*26811-78-9*] with a molecular mass ≥ca. 2000. This polyester can be cleaved to give sorbic acid in good yield [34] by either bases or acids (e.g., hydrochloric acid [35]);

alternatively, cleavage can be effected by metal-complex catalysts, [36].

The polyester is also suitable for the production of various sorbic acid derivatives. For example, in the presence of acidic esterification catalysts it can be reacted with alcohols to give sorbate esters [38].

The crude sorbic acid must be purified, generally by recrystallization from an aqueous solution [39], from a mixture of water and an alcohol or acetone [40], or from organic solvents that are immiscible with water, such as methyl acetate [41]. Treatment with organic solvents [42] and purification by steam distillation [43] have also been described.

5. Environmental Protection

Sorbic acid shows antimicrobial activity against many fungi, yeasts, and bacteria (see Chap. 8). However, this is only the case if the population of the target organisms is small. Many microorganisms are capable of degrading and metabolizing sorbic acid when present in large numbers [44], including gram-negative sulfate-reducing bacteria [45]. It is for this reason that sorbic acid is readily degradable in soil. Sorbic acid also shows high degradability (95 % within 6 d) in the Zahn – Wellens test (OECD 302 B). Sorbic acid and the sorbates are not hazardous with respect to water and are not subject to any hazardous materials classification.

The acute fish toxicity (LC_{50} for the zebra barbel) is very low (>1000 mg/L after 48 – 96 h). Thus, sorbic acid is incorporated in the lowest German water hazard class (WGK"0") [148].

At the normal application concentrations of 0.05 – 0.2 %, sorbic acid displays very little toxicity to plants. Neither the roots nor the aboveground portions are damaged, from which it can

be concluded that the ecotoxicity of the substance generally must be very low.

In the absence of local regulations to the contrary, sorbic acid and sorbates can be disposed of or incinerated along with household waste in the same way as foods.

6. Quality Specifications

Sorbic acid and sorbates are used almost exclusively in foods, animal feeds, cosmetics, and pharmaceuticals, and quality specifications are therefore adapted to the legal requirements applicable to these areas. In the EC the regulation of 2. December 1996, concerned specifically with additives is valid, which is based on an EC directive. The purity standards of the third edition of the Food Chemicals Codex are applicable in the United States. JECFA, a joint committee of experts from the United Nations Food and Agriculture Organization (FAO) and the World Health Organization (WHO) has also developed a set of purity specifications. Furthermore, sorbic acid and potassium sorbate are cited in various pharmacopeias.

All these requirements specify a purity of at least 99 % and limit the content of aldehydes, arsenic, and toxicologically relevant heavy metals. Neither sorbic acid nor its salts should show signs of discoloring during 90 min of heating at 105 °C.

7. Analysis

Steam distillation is a common method for the quantitative isolation of sorbic acid from the investigated material. For qualitative detection and quantitative determination the red coloration is used that sorbic acid produces with 2-thiobarbituric acid after oxidation with potassium dichromate to malonaldehyde. As a polyunsaturated compound, sorbic acid displays a pronounced absorption maximum at ca. 260 nm (depending on the pH of the solution), which can be likewise used for quantitative determination [84]. Various methods are described and published that utilize HPLC for analysis. For analyses in special foods see [85–88], for determination of sorbic acid in foods and cosmetics in general see [89–91].

Standardized methods of detecting sorbates (GC, TLC, and HPLC) have been published in the revised edition of the Swiss Foodstuffs Manual (1992). A method exists for detecting sorbates in liquid sweeteners in accordance with § 35 of the Federal German food law (L. 57.22.99). Rather unconventional techniques of detecting sorbic acid such as ion chromatography or capillary isotachophoresis [92] have not become established so far in routine use. X-ray structural analysis of sorbic acid has also been described [93].

8. Storage and Transportation

Sorbic acid and its salts can be stored for several months. They should be stored in a cool, dry environment with protection from light. This applies especially to finely powdered sorbates.

Sorbic acid and sorbates are not subject to any hazardous goods classification. They can be stored and transported in the same way as ordinary foods.

9. Legal Aspects

Sorbic acid is permitted worldwide as a preservative for foods. Approval lists differ considerably from country to country, however, because of differences in eating habits. In the United States sorbic acid and its salts (which includes the sodium, potassium, and calcium salts) are classified as "generally recognized as safe" (GRAS). (Sodium sorbate is not produced industrially and is generally not used because of its instability). In the EC sorbic acid is included as number E 200 in the list of approved preservatives, which also recognizes potassium sorbate (E 202) and calcium sorbate (E 203).

Sorbic acid is also permitted as an additive for animal feeds and cosmetics. Sorbic acid and potassium sorbate are listed in various pharmacopeias and are thus recognized as acceptable preservatives for pharmaceutical products as well.

10. Mode of Action and Uses

Certain potential uses for sorbic acid described in the patent literature (e.g., as a raw material

for chemical reactions or polymerizations) have remained unimportant in practice because of the relatively high cost of the substance. Sorbic acid and the sorbates are used almost exclusively as preservatives. Because of their lack of toxicity the main areas of application are in foods, animal feeds, tobacco, cosmetics, and pharmaceuticals, as well as in packing materials for these substances and in other products that come into contact with human or animal skin in some way. Sorbic acid, potassium sorbate, and especially calcium sorbate are also used in some technical applications [46].

Some details of the antimicrobial activity of sorbic acid remain unexplained [47], [48]. Sorbic acid inhibits many enzymes in the microbial cell, namely enolase and lactate dehydrogenase, which are involved in the carbohydrate metabolism [105]. Sorbic acid interferes also, though not very specifically, with enzymes of the citric acid cycle including succinate dehydrogenase, fumarase, aspartase, malate dehydrogenase, isocitrate dehydrogenase, and α-ketoglutanate dehydrogenase [106–108]. Sorbic acid also impairs the catalase/peroxidase system [109], [110] and enzymes containing a sulfhydryl group [111]. The primary centers of attack in the cell may differ in bacteria, yeasts, and fungi. In other reports, it has been increasingly assumed that sorbic acid is also active against the cell wall [49]. Thus, sorbic acid inhibits the absorption of amino acids in bacteria. Proton-flow into the cell also increases as a result of partial destruction of the cell membrane, requiring the cell to expend additional energy to compensate for the resulting potential differences [50]. Resistance in the true sense of the word (i.e., an increase in the limiting inhibiting concentration under the influence of subthreshold amounts of sorbic acid) is not observed in either *Echerichia coli* [51] or fungi [52]. Primarily the undissociated sorbic acid enters the cell wall of microorganisms, i.e., for food preservation the undissociated proportion of sorbic acid is most effective. Owing to its low dissociation constant sorbic acid, unlike other preservative acids, can also be employed for preserving weakly acid foods with a high pH. There are reasons to believe that also dissociated sorbic acid has an antimicrobial action. However this action is about 100 times weaker than that of the undissociated acid [112], [113].

Sorbic acid is a microbiostatic and not a microbiocidal agent. Sorbic acid activity is directed mainly toward yeasts and molds, including organisms responsible for aflatoxin formation [53]. Among bacteria, those that are catalase positive are inhibited more strongly than those that are catalase negative, with aerobic bacteria affected the most. However, bacteria can also be suppressed by a combined action of sorbic acid and other inhibiting factors [114–125]

Some microorganisms are capable of incorporating sorbic acid into their metabolism and thereby degrading it [44]. This is only possible, however, if sorbic acid is present below the threshold concentration and the microorganism population is very high. This means that sorbic acid is suitable for the preservation only of hygienically clean ingredients with low microorganism counts.

An important incentive for the use of sorbic acid and sorbates in foods is their virtual neutrality with respect to taste and odor, together with the fact that sorbic acid does not react with food components because of its chemical inertness.

The application concentration of sorbic acid is usually 500 – 2500 ppm. Higher concentrations are required the higher the pH of the product to be preserved. Low concentrations suffice if the system to be preserved is subject to other protective factors, such as low pH. In the case of wine ca. 50 – 200 ppm sorbic acid or a corresponding amount of potassium sorbate is adequate because the effectiveness is enhanced by the wine's low pH and the sulfur dioxide and ethanol present.

The favorable partition coefficient of sorbic acid between oil and water is important in the preservation of fat emulsions such as margarine or mayonnaise and cosmetic lotions. Thus, a relatively high proportion of the sorbic acid in an emulsion remains in the aqueous phase, which is alone susceptible to microbiological attack [54]. Sorbic acid is the agent of choice for the preservation of butter and margarine with a low fat content.

Sorbic acid and its salts are very important for preventing the development of mold in cheeses of all types. The activity of sorbic acid against agents responsible for mycotoxin formation plays a special role in this context [55]. Depending on the type of cheese, sorbic acid can be added to the cheese itself (cottage cheese, pro-

cessed cheese), potassium sorbate can be added to the salt bath, or the cheese surface can be treated with a solution of suspension of sorbic acid, potassium sorbate, or calcium sorbate (hard cheese). The role of fungistatic packaging materials and coating materials containing sorbic acid or its salts is diminishing [56].

Undesirable mold growth on hard sausages can be suppressed by treatment with 10 – 20 % potassium sorbate solution [57]. Replacement of the nitrite used in meat processing by sorbic acid has been widely discussed. While sorbic acid is inactive towards *Clostridium* species in neutral medium, (i.e., under optimal growth conditions) it does suppress the formation of toxins very effectively at lower pH (i.e., pH ca. 5.5) in concentrations of 0.1 – 0.2 %. Sorbic acid can be considered as a good alternative to nitrite from a microbiological viewpoint provided sodium chloride is present as well. However, the red coloration and the pickling aroma preferred in cured meats do not develop in the absence of nitrite, which has prevented the successful use of sorbic acid in this application [58–61]. The use of potassium sorbate in combination with ascorbic or others acids gives a good and long curing [126–129].

The addition of potassium sorbate to fermenting vegetables leads to a particularly pure fermentation, because sorbic acid inhibits the undesirable proliferation of molds more than it does the desired lactic acid fermentation [62], [63]. Sorbic acid is also used for preserving all types of fruit products, including prunes, fruit pulps, marmelades and jams, fruit juices, jellies, and candies. Potassium sorbate in combination with sulfur dioxide is very important for stabilizing wine against undesired after-fermentation.

Baked goods can be protected against mold formation by the addition of sorbic acid to the dough. In yeast products (e.g., bread) sorbic acid may disrupt the action of the yeast, but a special form of the acid, characterized by a coarser particle size, shows virtually no detrimental effect on yeast activity [64].

Sorbic acid and potassium sorbate are acquiring increasing importance in the preservation of cosmetic products [130] (especially baby care products). Because of their good efficacy, low toxicity, and good skin compatibility they are favorably estimated in the literature [131–136].

In accordance with the "hurdle theory" [137] a combination of sorbates with modern physical preservation methods [138], [139] or other preservatives can be advantageous [140].

11. Economic Aspects

Sorbic acid and its salts, particularly potassium sorbate, have been produced industrially since the mid-1950s, primarily in the United States, Japan, and the Federal Republic of Germany. In the mid-1990s world demand exceeded 30 000 t/a.

12. Toxicology

The LD_{50} value of sorbic acid is ca. 10 g per kilogram body weight for rats [65]. Other authors give an LD_{50} of 7.4 g [141], 8.7 g [142], or 7.5 g [143] per kilogram body weight. As an acid, sorbic acid causes irritation to the mucous membranes, but skin irritation is observed only with very sensitive individuals.

Sorbic acid was first introduced as a food preservative at a time when extensive toxicological testing for new food additives was already mandatory. For this reason numerous studies have been published on acute, subacute, subchronic, and chronic tolerance (for a summary see [1, vol. II, pp. 13 – 31], [2, pp. 205 – 224] and [66], [67]). Sorbic acid has probably undergone the most thorough toxicological investigations of any preservative.

The allergenic potential of sorbic acid is extremely low, since, as a low molecular substance, it cannot cause an antibody response. Moreover, formation of covalent bonds with proteins, which might result in immediate hypersensitivity, is not known [144]. Pseudo-allergic reactions to sorbic acid as a food additive are relatively rare [145–147].

The presence of 10 % sorbic acid in rat feed causes increased growth and an increase in liver weight in the subchronic test, but no other damage [68]. The increase in liver weight observed at these high dose levels is interpreted as hypertrophy caused by excess work [69]. The increase in weight can be traced back to sorbic acid's caloric value.

Rats tolerate the lifelong addition of 5 % sorbic acid to their feed [69]. Carcinogenesis studies (rats, oral exposure, two years) have

shown that low concentrations of sorbic acid (1.5 – 10 % in the feed) produce no abnormalities compared with control animals with respect to growth, blood count, and the state and function of 12 internal organs. Adding 10 % sorbic acid to the feed leads to somewhat less weight gain and an increase in the size of the thyroid, liver, and kidneys [70]. Similar results have been obtained with mice [71].

Sorbic acid is not teratogenic [72]. All mutagenicity and genotoxicity investigations have also produced negative results [67], [73–77]. Sorbic acid is also not carcinogenic [70], [71].

Sorbic acid is metabolized like other fatty acids; degradation occurs via the typical β-oxidation pathway [69], [78, 79].

The allergy-producing potentials and phototoxicities of both sorbic acid and potassium sorbate are extraordinarily low. Just one case is of allergic reaction has been reported (a type 4 allergic reaction with a low impact on the patient) [147], although sorbic acid has been used for more than 40 years all over the world. The CIR (Cosmetic Ingredient Review) Expert Panel of the Cosmetic, Toiletry, and Fragrance Association (CTFA) has classified both substances as "safe" at concentrations and under conditions typical for cosmetic agents [80].

In the case of sodium sorbate, which is not utilized in foods because of its tendency to undergo oxidation, more recent studies have demonstrated a low level of genetic toxicity potential in vitro (e.g., micronuclei induction, sister chromatid exchanges). No analogous effects are observed with sorbic acid or potassium sorbate [81], [82], [135], [149].

1. Introduction

Spasmolytic agents are substances that relieve spasms of smooth muscle. This effect can be achieved by compounds that attack the parasympathetic nervous system (parasympatholytic = neurotropic spasmolytic agents) or by substances that act directly on the smooth muscles (musculotropic spasmolytic agents). Like the heart and glands, the smooth muscle of the intestines, blood vessels, and eyes is innervated by the autonomic (visceral) nervous system (→ Neuropharmacology). The peripheral autonomic system consists of three parts: the sympathetic, the parasympathetic, and the enteric nervous systems (Fig. 1). The sympathetic and parasympathetic peripheral nerve pathways are each composed of two neurons. The first (preganglionic) neuron conducts impulses from the central nervous system to an autonomic ganglion; here transmission is effected to the second (postganglionic) neuron, leading ultimately to the organ of response.

Transmission of impulses in all the ganglia is mediated by the neurotransmitter acetylcholine which especially activates nicotinic receptors as well as secondary muscarinic M_1/M_2 receptors (see below and → Neuropharmacology, Chap. 5.1.) located on cell bodies of the postganglionic neurons and neurons of the enteric nervous system. Blockage of the nicotinic receptors is achieved by means of *ganglia blockers*, most of which are quaternary ammonium salts. The transmission of postganglionic neuron impulses to the organ of response occurs, in sympathetic fibers, via noradrenaline as the neurotransmitter together with adrenoceptors. In parasympathetic fibers, however, acetylcholine is the transmitter and the receptors are exclusively muscarinic (see Section 2.1).

The enteric nervous system includes neurons in the walls of the gastrointestinal tract from the beginning of the esophagus to the sphincter ani internus, as well as neurons of the pancreas and the bile duct. It controls motility and secretion in all the various sections of the food passage. The enteric nervous system is capable of carrying out its function without any influence from the central nervous system. Indeed, the sympathetic and parasympathetic systems exert only modulating effects. In many neurons, especially neurons of the enteric nervous system, there are other transmitter substances in addition to the classical neurotransmitters noradrenaline and acetylcholine. These substances are released either alone or in combination with noradrenaline and acetylcholine (cotransmission) [1–4]. Examples of acetylcholine cotransmitters include vasoactive intestinal polypeptide (VIP) and sub-

stance P, which belongs to the group known as tachykinins.

2. Parasympatholytics (Neurotropic Spasmolytic Agents)

Parasympatholytics block the acetylcholine-mediated transmission of impulses from postganglionic parasympathetic fibers to the organ of response by competitive antagonism at the muscarinic receptors. Due to the resulting relaxing effect on the smooth muscles, these substances are also called *neurotropic spasmolytic agents*.

2.1. Muscarinic Receptors

It has been possible with the help of functional pharmacological investigations and radio-ligand binding studies to identify four subtypes of muscarinic receptors ($M_1 - M_4$). This heterogeneity of the muscarinic receptors was confirmed in an impressive manner by the cloning, sequencing, and expression of five muscarinic receptor genes ($m_1 - m_5$). A great similarity was found between the binding properties for muscarinic ligands coupling to various effector systems, and the localization of pharmacologically characterized native $M_1 - M_4$ receptors, on the one hand and the molecularly defined $m_1 - m_4$ receptors (the $m_1 - m_4$ gene products) on the other. Pharmacological characterization of the (molecularly defined) m_5 receptor has not yet been accomplished ([5]; for reviews see [6–9]). All the subtypes known to date belong to the "superfamily" of membrane-bound receptors coupled to G-proteins (see review articles [10], [11]).

Muscarinic receptors are widely distributed in the central and peripheral nervous systems as well as in the parasympathetically innervated organs of response. All five subtypes occur in the central nervous system. M_1 and M_2 receptors have been found in the sympathetic and parasympathetic ganglia and in the interneu-

ronal synapses of the enteric nervous system; these modulate the neurotransmission that is primarily mediated at these sites via nicotinic receptors. The function of peripheral effector organs or cells is influenced largely by the presence of postsynaptic M_2 and M_3 receptors: the heart possesses predominantly M_2 receptors which, when stimulated, cause a decrease in both the heart rate and the force of contraction. M_3 receptors on gland cells mediate increases in secretion. The smooth muscle of the respiratory tract, gastrointestinal tract, and urinary bladder contains a heterogeneous population of M_2 (high density) and M_3 (low density) receptors. However, the receptor that mediates contraction of these organs is, in all probability, the M_3 subtype, while the function of the M_2 receptors on these organs is still not understood ([12]; for review articles, see [6–9]). Figure 2 shows the largely proved intracellular reaction sequence that leads finally to contraction of smooth muscle after stimulation of the M_3 receptors [6], [13]. After binding the endogenous agonist acetylcholine (ACh), the receptor stimulates phospholipase C via a G-protein (G). This cleaves a special membrane phospholipid (phosphatidylinositol-4,5-diphosphate, PIP_2) to give inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). The Ca^{2+} ions released by IP_3 from the sarcoplasmic reticulum (SR) trigger contractions of the contractile apparatus of the cell. Phosphorylation of IP_3 to IP_4, and the protein kinase C activated by DAG probably cause an additional Ca^{2+} influx from the extracellular space.

Muscarinic antagonists compete with the endogenous agonist acetylcholine for its binding site on the receptor (i.e., they also possess affinity). However, in contrast to acetylcholine, they do not trigger any successive reactions (i.e., they lack intrinsic activity). This is the mode of action for neurotropic spasmolytic agents.

However, none of the substances described below possesses the desirable property of subtype-selective blockage of the M_3 receptors that mediate contraction. The largely nonselective blockage of all muscarinic receptor subtypes (including, for example, cardiac M_2 receptors) explains some of the side effects and treatment restrictions associated with classical parasympatholytics. For the control of spasms of smooth muscle, the development of subtype-selective antagonists would open the way to more efficient therapy with fewer side effects (see Chap. 5).

2.2. Therapy

Parasympatholytics are indicated for:

1) Spasms of the smooth muscle of the gastrointestinal tract (e.g., in the case of stomach and duodenal ulcers, spastic obstipation, and pylorospasm)
2) Spasms of the bile and urinary duct (e.g., gall-stone and kidney-stone colics)
3) Spasms in the region of the female genital organs (e.g., severe dysmenorrhea)
4) Spasms in the region of the respiratory tract (especially in bronchial asthma; see → Antiasthmatic Agents)
5) Urinary incontinence as a result of detrusor instability and "neurogenic bladder"

Parasympatholytics are used not only as antispasmodic agents, but also in the treatment of Parkinson's disease (→ Parkinsonism Treatment), in bradycardic arrhythmias, and in the preparation of patients for anesthesia. Although classical parasympatholytics were used frequently in the past for the treatment of stomach and duodenal ulcers, they have in the course of time been replaced by pirenzepine [*28797-61-7*], an antagonist affecting mainly M_1 receptors, as well as other ulcer drugs (histamine-H_2 antagonists and inhibitors of H^+/K^+-ATPase; see → Antiulcer Drugs).

Parasympatholytics containing tertiary nitrogen are rapidly absorbed when administered orally. On the other hand, the absorption of quaternary ammonium compounds is poor. Achieving an adequate effect with these compounds frequently requires parenteral application or oral doses that are substantially higher in comparison with i.v. administration. The main advantage of quaternary ammonium compounds is that they are virtually incapable of crossing the blood – brain barrier because of their low lipid solubility; therefore, unlike the tertiary compounds, they are centrally inactive. However, the quaternary compounds often also act as antagonists of nicotinic receptors. Therefore, when high doses are administered, symptoms of ganglia blockage can supervene on the effects of muscarinic-receptor blockage.

Figure 2. Schematic representation of the intracellular reaction sequence which, after stimulation of the M_3 receptors, ultimately causes contraction of the smooth muscles [modified after K. Starke and D. Palm (1992)].

As a result of the absence of receptor and organ selectivity in classical parasympatholytics, the following side effects must be expected:

1) Increase in the cardiac rate
2) Reduced secretion of saliva
3) Dilation of the pupils and disturbances of visual accommodation
4) Disturbances of urination

Parasympatholytics are contraindicated in narrow-angle glaucoma and prostate adenoma. In the presence of coronary heart disease, these substances may be administered only in doses that do not increase the cardiac rate.

2.3. Therapeutic Agents

Parasympatholytics can be divided chemically into tropane alkaloids and related substances (atropine, homatropine, scopolamine, and their quaternary derivatives, see→ Alkaloids, Chap. 4.) and substances with diverse chemical structures.

2.3.1. Tropane Alkaloids and Related Substances

Atropine [*51-55-8*], 3α(1α*H*,5α*H*)-tropanyl-(±)-tropate, (±)-hyoscyamine, $C_{17}H_{23}NO_3$, M_r 289.38, (±)-form *mp* 114–116 °C, (−)-form *mp* 108.5 °C, $[\alpha]_D^{20}$ −21.0° (EtOH); methobromide [*2870-71-5*], $C_{18}H_{26}BrNO_3$, M_r 384.33, *mp* 222–223 °C; methonitrate [*52-88-0*], $C_{18}H_{26}N_2O_6$, M_r 366.42, *mp* 163 °C; sulfate [*55-48-1*] (anhydrous), [*5908-99-6*] (monohydrate), $(C_{17}H_{23}NO_3)_2$, H_2SO_4, H_2O, M_r 694.82, *mp* 190–194 °C.

Atropine is a tropane alkaloid that occurs in *Atropa belladonna L.*, *Datura stramonium L.*, and other *Solanaceae* species, and it is still

one of the most important parasympatholytic agents (for synthesis, see [14] and → Alkaloids, Chap. 4.).

Trade Names. Atropine: Atropinol (Winzer, FRG); borate: Borotropin (Winzer, FRG); methonitrate: Ansudoral (Basotherm, FRG), Tonaton (Luitpold, FRG); sulfate: Atropen (Survival, USA), Atropisol (Cooper Vision, USA), Atropocil (Edol, Portugal), Atrosol (Liba, Turkey), Isopto-Atropine (Alcon: Sweden, UK, USA), Liotropina (Sifi, Italy), MIN-I-JET Atropinsulfat (Braun, FRG), Skiatropine Blache (Novopharma, Switzerland).

Butropium bromide [*29025-14-7*], 8-(4-butoxybenzyl)-3α-[(*S*)-(−)-tropoyloxy]-1αH,5α *H*-tropanium bromide, $C_{28}H_{38}BrNO_4$, M_r 532.53, *mp* 166 – 168 °C. Synthesis: the alkaloid hyoscyamine (→ Alkaloids, Chap. 4.1.) is quaternized with 4-butoxybenzyl bromide in 2-propanol [15]. White crystals are obtained, which have a bitter taste and are readily soluble in water. Used in Japan, butropium bromide is a quaternary derivative of atropine with atropine-like peripheral effects.

Trade Name. Coliopan (Eisai, Japan).

Butylscopolaminium bromide [*149-64-4*], *N*-butylscopolaminium bromide, hyoscine butylbromide, *N*-butyl-6β,7β-epoxy-3α-(−)-tropoyloxy-1αH,5αH-tropanium bromide, $C_{21}H_{30}BrNO_4$, M_r 440.40, *mp* 142 – 144 °C, $[\alpha]_D^{20}$ −20.8° (3 % in water). Synthesis: the alkaloid scopolamine (→ Alkaloids, Chap. 4.1.) is quaternized as described in [16] to produce white, odorless, light-sensitive crystals, which have a bitter taste and are highly soluble in water and ethanol. Butylscopolaminium bromide is a frequently used quaternary derivative of scopolamine; it was introduced to therapy in 1950.

Trade Names. Buscapina (Boehringer Ingelheim,Spain), Buscopan (Boehringer Ingelheim: Belgium, Denmark, FRG, Greece, Italy, the Netherlands, Portugal, Switzerland; Delagrange, France), Buscotek (Tek, Turkey), Hyosin (Otsuka, Japan), Moryspan (Beppu, Japan), Vagotrope S (Infar, Portugal).

Homatropine methylbromide [*80-49-9*], 8-methyltropinium bromide mandelate, $C_{17}H_{24}BrNO_3$, M_r 370.29, *mp* 191 – 192 °C (partial decomp.). Homatropine, which was first used therapeutically in 1883, has gained wide acceptance as a locally applied mydriatic, but the *N*-quaternary methylbromide [17] is seldom used today.

Trade Names. Nopar (Uni-Pharma, Greece), Novatropina (Asta-Medica, Italy).

Octatropine methylbromide [*80-50-2*], *N*-methyl-*O*-(2-propylvaleryl)tropinium bromide, $C_{17}H_{32}BrNO_2$, M_r 362.37, *mp* 329 °C; methylchloride $C_{17}H_{32}ClNO_2$, *mp* 289 °C. For synthesis, see [18].

Trade Names. Valpin (Endo, USA; Sankyo, Japan).

Trospium chloride [*10405-02-4*], 3α-benziloyloxyspiro[nortropane-8,1′-pyrrolidinium] chloride, 3α-hydroxyspiro[1αH,5αH-nortropane-8,1′-pyrrolidinium] chloride benzilate, $C_{25}H_{30}ClNO_3$, M_r 427.97, *mp* 255 – 257 °C (decomp.). It is prepared by heating the benzilic acid ester of nortropine with 1,4-dichlorobutane in acetonitrile [19].

Trade Names. Relaspium (Isei, Japan), Spasmex (Pfleger, FRG), Spasmo-lyt (Madaus, FRG); present in Spasmo-Urgenin (Madaus, FRG).

2.3.2. Substances with Diverse Chemical Structures

Clidinium bromide [*3485-62-9*], 3-benziloyloxy-1-methylquinuclidinium bromide, $C_{22}H_{26}BrNO_3$, M_r 432.38, *mp* 240 – 241 °C. Synthesized by the reaction of diphenylglycolyl chloride with 3-hydroxyquinuclidine, followed by quaternization with methyl bromide. 3-Hydroxyquinuclidine is in turn formed by the reduction of 3-oxoquinuclidine [20]. White, slightly light-sensitive crystals, are formed which are soluble in water and ethanol. Clidinium bromide was first used therapeutically in 1953. It is administered either alone or in combination with chlordiazepoxide in the symptomatic treatment of peptic ulcers and other gastrointestinal functional disorders.

Trade Names. Quarzan (Hoffmann-La Roche, USA), contained in Clipoxide (Schein, USA), Corium (ICN, Canada), Librax (Hoffmann-La Roche: Australia, Canada, FRG, USA), Libraxin (Hoffmann-La Roche, UK).

Diphemanil methylsulfate [*62-97-5*], 4-benzhydrylidene-1,1-dimethylpiperidinium methylsulfate, $C_{21}H_{27}NO_4S$, M_r 389.50, *mp* 194 – 195 °C. For synthesis, see [21], [22]. It is soluble in water (1 : 33), ethanol, and chloroform. Diphemanil is also used externally as a 2 % cream in the treatment of profuse perspiration.

Trade Names. Prantal (Schering-Plough, Italy; Unicet, France).

Emepronium bromide [*3614-30-0*], (±)-*N*-ethyl-*N*,*N*-dimethyl-(4,4-diphenyl-2-butyl) ammonium bromide, $C_{20}H_{28}BrN$, M_r 362.37, *mp* 204 °C. For synthesis, see [23], [24]. Emepronium bromide is used in the racemic form mainly in the treatment of urinary incontinence and spasms of the bladder and ureter. The enantiomers of this substance show practically no receptor- or stereoselectivity in vitro [25].

Trade Names. Cetiprin (Globopharm, Switzerland; Kabi Pharmacia: Austria, Denmark, Sweden; KabiVitrum: Finland, UK), Detrulisin (Glaxo-Allen, Italy); as the carrageenate: Uro-Ripirin (Fresenius, FRG).

Fenpiverinium bromide [*125-60-0*], 1-(3-carbamoyl-3,3-diphenylpropyl)-1-methylpiperidinium bromide, $C_{22}H_{29}BrN_2O$, M_r 417.41,

mp 177 – 179 °C. The synthesis is described in [26].

Glycopyrronium bromide [*596-51-0*], (±)-3-(α-cyclopentylmandeloyloxy)-1,1-dimethylpyrrolidinium bromide, glycopyrrolate, $C_{19}H_{28}BrNO_3$, M_r 398.36, *mp* 193.2 – 194.5 °C. Synthesized by the esterification of α-cyclopentylmandelyl chloride with 1-methyl-3-pyrrolidinol, followed by quaternization [27]. It is soluble in water (1 : 4.2) and ethanol (1 : 30), slightly soluble in chloroform, and practically insoluble in ether.

Trade Names. Robinul (Robins: Finland, Switzerland, Sweden, UK, USA; Brenner/Efeka, FRG; Kaken, Japan; Rorer, the Netherlands; Wyeth, Denmark), Tarodyl (Lundbeck, Finland), Tarodyn (Lundbeck, Sweden).

Hexocyclium methylsulfate [*115-63-9*], 4-(β-cyclohexyl-β-hydroxyphenethyl)-1,1-dimethylpiperazinium methylsulfate, $C_{21}H_{36}N_2O_5S$, M_r 428.59, *mp* 200 – 210 °C. For synthesis, see [28].

Trade Name. Tral (Abfar, Turkey; Abbott, USA).

Isopropamide iodide [*71-81-8*], (3-carbamoyl-3,3-diphenylpropyl)diisopropylmethylammonium iodide, $C_{23}H_{33}IN_2O$, M_r 480.42, *mp* 198 – 201 °C (decomp.). Formed by the reaction of diphenylacetonitrile with diisopropylaminoethyl chloride, followed by hydrolysis of the nitrile to the amide function and quaternization [29]. White to yellowish, odorless, light-sensitive crystals are obtained, which have a bitter taste and are soluble in water (1 : 50), ethanol (1 : 10), and chloroform (1 : 5), but only very slightly soluble in ether. This quaternary anticholinergic, which is mainly found in combination preparations, exhibits atropine-like peripheral effects. The antispasmodic and antisecretory effect of a single dose of 5 – 10 mg lasts up to 12 h.

Trade Names. Darbid (Smith Kline & French: Canada, USA), Priamide (Janssen: Belgium, the Netherlands), Tyrimide (Smith Kline & French: Australia, UK); present in Combid (Smith Kline & French: Canada, USA), Prochlor-Iso (Schein, USA), Pro-Iso (Geneva, USA), Stelabid (Smith Kline & French: Australia, Canada, UK).

Mepenzolate bromide [*76-90-4*], 3-benziloyloxy-1,1-dimethylpiperidinium bromide, $C_{21}H_{26}BrNO_3$, M_r 420.37, *mp* 228 – 229 °C (decomp.). Made from benzilic acid and 3-chloro-1-methylpiperidine, followed by quaternization of the resulting intermediate with methyl bromide [30]. It is a white or yellowish powder, soluble in water (1 : 110), absolute ethanol (1 : 120), and methanol (1 : 8).

Trade Names. Cantil (Sigma, Australia; Draco, Sweden; MCP, UK; Merrel Dow: Belgium, USA; Roger Bellon, France), Cantril, Colibantil, Colum (manufacturer unknown, Italy),

Tralanta (Sawai, Japan), Trancolon (Fujisawa, Japan), Trokonil (Taiyo, Japan).

Methanthelinium bromide [*53-46-3*], *N*,*N*-diethyl-*N*-methyl-2-(9-xanthenylcarbonyloxy) ethylammonium bromide, $C_{21}H_{26}BrNO_3$, M_r 420.36, *mp* 175 – 176 °C. Prepared from 9-xanthenecarboxylic acid and 2-diethylaminoethanol [31]. Methanthelinium bromide has been largely replaced in clinical practice by its more potent derivative propantheline bromide.

Trade Names. Banthine (Searle, USA), Vagantin (Palmicol, FRG).

Otilonium bromide [*26095-59-0*], *N*,*N*-diethyl-*N*-methyl-*N*-{2-[4-(2-octyloxybenzamido)-benzoyloxy]ethyl}ammonium bromide, $C_{29}H_{43}BrN_2O_4$, M_r 563.57, *mp* 166 – 168 °C. For synthesis, see [32].

Trade Names. Spasmoctyl (Menarini, Spain), Spasmomen (Menarini, Italy).

Oxapium iodide [*6577-41-9*], (±)-1-[(2- cyclohexyl-2-phenyl-1,3-dioxolan-4-yl)methyl]-1-methylpiperidinium iodide, cyclonium iodide, $C_{22}H_{34}INO_2$, M_r 471.42, *mp* 195 – 197 °C (α-form, from isopropanol or chlorobenzene), *mp* 150 – 152 °C (β-form, from chlorobenzene). For synthesis, see [33].

Trade Name. Esperan (Toyama, Japan).

Oxyphenonium bromide [*50-10-2*], *N*,*N*-diethyl-*N*-[2-(α- cyclohexylmandeloyloxy) ethyl]- *N*-methylammonium bromide, $C_{21}H_{34}BrNO_3$, M_r 428.41, *mp* 189 – 194 °C. For synthesis, see [34].

Trade Names. Antrenyl (Ciba: Belgium, the Netherlands, Switzerland, Turkey, USA), Spasmophen (Polfa, Poland), Subranyl (Vita, Greece)

Parapenzolate bromide [*5634-41-3*], 4-benziloyloxy-1,1-dimethylpiperidinium bromide, $C_{21}H_{26}BrNO_3$, M_r 420.37, *mp* 231 – 232 °C. For synthesis, see [35]. Parapenzolate bromide is a structural isomer of mepenzolate bromide, with similar activity.

Trade Name. Spacine (Unicet, France).

Prifinium bromide [*4630-95-9*], 3-(diphenylmethylene)-1,1-diethyl-2-methylpyrrolidinium bromide, $C_{22}H_{28}BrN$, M_r 386.39, *mp* 216–218 °C. For synthesis, see [36].

Trade Names. Padrin (Fujisawa, Japan), Riabal (Logeais, France; IBI, Italy).

Propantheline bromide [*50-34-0*], *N*,*N*-diisopropyl-*N*-methyl-*N*-[2-(9-xanthenecarbonyloxy)-ethyl]ammonium bromide, $C_{23}H_{30}BrNO_3$, M_r 448.42, *mp* 159 – 161 °C. Prepared by reacting xanthene-9- carboxylic acid chloride with 2-diisopropylaminoethanol,

followed by alkylation with methyl bromide [31]. White, odorless crystals, freely soluble in water, ethanol, and chloroform. Propantheline bromide was introduced to clinical practice in 1953, and is used in the treatment of peptic ulcers, visceral spasms, and enuresis.

Trade Names. Corrigast (Heumann, FRG), Ercoril (Ercopharm: Denmark, Finland), Pro-Banthine (Searle: Belgium, Denmark, France, Greece, the Netherlands, Sweden, Switzerland, USA).

Tiemonium iodide [*144-12-7*], (±)-4-[3-hydroxy-3-phenyl-3-(2-thienyl)propyl]-4-methylmorpholinium iodide, $C_{18}H_{24}INO_2S$, M_r 445.38, *mp* 189 – 191 °C; methylsulfate $C_{19}H_{27}NO_6S_2$, M_r 429.56. For synthesis, see [37].

Trade Names. Visceralgina (SIT, Italy), Visceralgine (Exel Pharma, Belgium; Remek, Greece).

Tridihexethyl chloride [*4310-35-4*], (±)-*N*-(3-cyclohexyl-3-hydroxy-3-phenylpropyl)-*N*-,*N*-,*N*-triethylammonium chloride, $C_{21}H_{36}ClNO$, M_r 353.97, *mp* 196 – 202 °C; iodide [*125-99-5*], $C_{21}H_{36}INO$, M_r 445.44, *mp* 179 – 184 °C. For synthesis, see [38].

Trade Name. Pathilon (Lederle, USA).

3. Musculotropic and Neurotropic–Musculotropic Spasmolytic Agents

Independent of autonomic innervation, smooth muscle can also be relaxed by direct action on the muscle cells. Drugs that act in this manner are named musculotropic or papaverine-like spasmolytic agents, after the opium alkaloid papaverine, which was the first known example.

Beginning in 1930, systematic modification of the papaverine molecule led to numerous other substances, including ethaverine and moxaverine, that are clearly superior to papaverine in potency but less toxic. Substances introduced later into clinical practice deviated more and more from the structure of the opium alkaloid (e.g., mebeverine, camylofin, and hymecromone). Interestingly, it was assumed as early as 1934 that papaverine-like spasmolysis depends less on the structure of the substance than on its ability to reduce surface tension [39], [40]. The mechanism of action of papaverine is not yet fully understood. Effects that have been detected include nonselective inhibition of phosphodiesterases [41] with a subsequent increase in the intracellular concentration of cyclic adenosine monophosphate (cAMP), a sodium-dependent cAMP-mediated Ca^{2+} efflux [42], the inhibition of extracellular Ca^{2+} influx (calcium channel antagonism), interaction with the intracellular release and storage of Ca^{2+} (papaverine and thiphenamil [43]), and inhibition of adenosine reuptake carriers [44]. Terolidine and oxybutynin exhibit not only parasympatholytic properties, but also marked calcium-channel blocking properties [45], [46]. In this respect they resemble the "calcium antagonists" used in hypertension and coronary insufficiency (→Calcium Antagonists).

The relaxing effect of musculotropic spasmolytic agents extends to all smooth muscle; i.e., to the vascular smooth muscle as well as the bronchial and intestinal smooth muscle. Consequently, preparations from within this group of substances are indicated in the treatment of spasms of the gastrointestinal tract, uterus, bronchi, bile duct, and urinary passage. As a result of the nonselective relaxing effect on smooth muscles described above, cardiovascular side effects (fall in blood pressure, arrhythmias) must

be anticipated, especially with intravenous administration.

Numerous substances, such as oxybutynin or camylofin, occupy an intermediate position between parasympatholytics and musculotropic spasmolytics. Since they show both parasympatholytic properties and the ability to relax smooth muscles directly they are also called *neurotropic – musculotropic spasmolytic agents*.

3.1. Musculotropic Spasmolytic Agents

Papaverine [*58-74-2*], 6,7-dimethoxy-1-(3,4-dimethoxybenzyl)isoquinoline, $C_{20}H_{21}NO_4$, M_r 339.38, *mp* 147 °C; hydrochloride [*61-25-6*], $C_{20}H_{22}ClNO_4$, M_r 375.84, *mp* 220 – 225 °C; sulfate [*32808-09-6*], $(C_{20}H_{21}NO_4)_2\ H_2SO_4$, M_r 866.90. Papaverine is a companion alkaloid (ca. 0.8 %) of opium. Numerous syntheses have been described (→ Alkaloids, Chap. 4.2.). The hydrochloride is soluble in water (1 : 30 – 1 : 40), ethanol (1 : 120), and chloroform, but practically insoluble in ether. As a result of its weak effect, papaverine is seldom used today as an antispasmodic agent, but it has regained importance in the treatment of erectile malfunctions (intracavernous self injection, SKAT therapy).

Trade Names. Cerebid (Saron, USA), Myobid (Laser, USA), Opdensit (Pharma Stroschein, FRG), Panergon (Mack/Illertissen, FRG; Pfizer, Switzerland), Pavabid (Marion, USA), Pavakey (Key, USA), Paveron (Linden, FRG).

Ethaverine [*486-47-5*], 6,7-diethoxy-1-(3,4-diethoxybenzyl)isoquinoline, ethylpapaverine, $C_{24}H_{29}NO_4$, M_r 395.48, *mp* 99 – 101 °C; hydrochloride [*985-13-7*], $C_{24}H_{30}ClNO_4$, M_r 431.94, *mp* 186 – 188 °C (decomp.). For synthesis, see [47] and [48]. Ethaverine is the tetraethyl homolog of papaverine.

Trade Names. United States: Circubid (Merchant), Eta-Lent (Roger), Ethaquin (Ascher), Ethatab (Glaxo), Ethaverol (Pharmex), Isovex (US Chemical), Pavaspan (Jamieson-McKames), Spasodil (Rand); Elzym (Luitpold, FRG), Olren (Heumann, FRG).

Moxaverine [*10539-19-2*], 1-benzyl-3-ethyl-6,7-dimethoxyisoquinoline, Eupaverin, $C_{20}H_{21}NO_2$, M_r 307.38, *mp* 78 – 79 °C; hydrochloride [*1163-37-7*], $C_{20}H_{22}ClNO_2$, M_r 343.84, *mp* 208 – 214 °C (decomp.). For synthesis, see [49].

Trade Names. Eupaverin (Merck: Sweden, Switzerland), Eupaverina (Bracco, Italy), Kollateral (Ursapharm, FRG).

Benzyl mandelate [*890-98-2*], (±)-benzyl 2-phenylglycolate, $C_{15}H_{14}O_3$, M_r 242.27, *mp* 93.6 °C. Colorless, odorless crystals are formed from reaction of the sodium salt of mandelic acid with benzyl chloride, or by esterification of the acid [50]. The crystals are insoluble in water but readily soluble in ethanol, acetone, ether, and chloroform. Like ethyl, isopentyl, and methyl mandelates, benzyl mandelate exhibits weak spasmolytic and analgetic effects. Benzyl mandelate is present in certain combination preparations, and is used mainly in Germany.

Trade Names. Doppel-Spalt N (Much, FRG), Govil (Stada, FRG), Tispol (Woelm, FRG).

Caroverine [*23465-76-1*], 1-[2-(diethylamino) ethyl]-3-(4-methoxybenzyl)-2(1*H*)-quinoxalinone, Spadon, $C_{22}H_{27}N_3O_2$, M_r 365.46, *mp* 69 °C, *bp* 202 °C (1.33 Pa); hydrochloride, $C_{22}H_{28}ClN_3O_2$, M_r 401.90, decomposition at 188 °C. For synthesis, see [51].

Trade Name. Spasmium (Donau-Pharmazie, Austria).

Flopropione [*2295-58-1*], 2′,4′,6′-trihydroxypropiophenone, $C_9H_{10}O_4$, M_r 182.17, *mp* 175 – 176 °C (anhydrous). Made by reacting benzene-1,3,5-triol with propionitrile in the presence of HCl and $ZnCl_2$, followed by hydrolysis of the resulting ketimine hydrochloride [52]. It is soluble in ethanol and ether and slightly soluble in cold water. Introduced in 1963, flopropione is used primarily in Japan in the treatment of gastrointestinal spasms and as a therapeutic agent for the liver and gallblader.

Trade Names. Japan: Bilup (Hishiyama), Cospanon (Eisai), Padeskin (Ohta), Pellegal (Mitsui), Spasmoril (Marupi), Spasmorin (Tokyo Tanabe), Supanate (Nippon Shinyadu); Labrodax (Rhodia, Argentina, Belgium).

Hymecromone [*90-33-5*], 7-hydroxy-4-methylcoumarin, $C_{10}H_8O_3$, M_r 176.16, *mp* 194 – 195 °C; sodium salt, $C_{10}H_7NaO_3$, M_r 198.14. It is made by a Pechmann reaction of resorcinol with ethyl acetoacetate [53], or as described in [54], [55]. Hymecromone is used as a choleretic agent and in the treatment of spasms of the bile duct.

Trade Names. Bilicanta (Boehringer Mannheim, Spain), Cantabiline (Lipha/Sophar, Belgium; Aron-Medicia, France), Cholonerton (Dolorgiet, FRG), Cholspasmin (Lipha, FRG), Gallo-Merz Spasmo Hymecromon (Merz, FRG), Himecol (Kissei, Japan).

Mebeverine [*3625-06-7*], (±)-5-ethyl-6-methyl-7-(4-methoxyphenyl)-5-azaheptyl 3,4-dimethoxy-benzoate, 4-[ethyl(*p*-methoxy-α-methylphenethyl)-amino]butyl veratrate, $C_{25}H_{35}NO_5$, M_r 429.54; hydrochloride [*2753-45-9*], $C_{25}H_{36}ClNO_5$, M_r 466.02, *mp* 105 – 107 °C (from 2-butanone). For the preparation of mebeverine, *N*-ethyl-*p*-methoxy-α-methylphenethylamine is reacted with succinyl chloride, the intermediate is reduced with lithium aluminum hydride, and the resulting alcohol is esterified with veratryl chloride [56]. Used therapeutically since 1961, mebeverine is employed in the treatment of colon irritabile, spastic colitis, etc.

Trade Names. Colofac (Cilag, Australia; Duphar, South Africa, UK; Kali-Pharma, Austria), Duspatal (Duphar: FRG, the Netherlands, Portugal), Duspatalin (Duphar: Belgium, France, Greece, Spain; Ferrosan, Denmark; Kali-Duphar, Switzerland).

Tiropramide [*55837-29-1*], (±)-2-benzamido-3-[4-(2-diethylaminoethoxy)phenyl]-*N,N*-dipropyl-propionamide, $C_{28}H_{41}N_3O_3$, M_r 467.66, *mp* 65 – 67 °C; hydrochloride, $C_{28}H_{42}ClN_3O_3$, M_r 504.12. For synthesis, see [57].

Trade Names. Alfospas (Opfermann, FRG; Rottapharm, Italy), Maiorad (Delta, Portugal; Merck Sharp & Dohme, Italy).

Trimebutine [*39133-31-8*], (±)-2-dimethylamino-2-phenylbutyl 3,4,5-trimethoxybenzoate, $C_{22}H_{29}NO_5$, M_r 387.48, *mp* 78 – 80 °C; hydrochloride, $C_{22}H_{30}ClNO_5$, M_r 423.95, *mp* 184 °C; hydrogenmaleate [*34140-59-5*], $C_{26}H_{33}NO_9$, M_r 503.50, *mp* 105 – 106 °C. The water-soluble hydrochloride is formed by heating 2-phenyl-2-dimethylaminobutanol with 3,4,5-trimethoxybenzoyl chloride in benzene [58].

Trade Names. As the maleate: Debridat (Armstrong, Argentina; Lab. Jouveinal, France; Sigmatau, Italy), Polibutin (Juste, Spain).

3.2. Neurotropic – Musculotropic Spasmolytic Agents

Bietamiverine [*479-81-2*], 2-diethylaminoethyl (2-phenyl-2-piperidine)acetate, $C_{19}H_{30}N_2O_2$, M_r 318.45, *bp* 65 °C (133.3 Pa); dihydrochloride [*2691-46-5*], $C_{19}H_{32}Cl_2N_2O_2$, M_r 391.38, *mp* 194 – 195 °C. For syntheses, see [59], [60].

Camylofin [*54-30-8*], 3-methylbutyl 2-[(*N*-2-diethylaminoethyl)amino]-2-phenylacetate, $C_{19}H_{32}N_2O_2$, M_r 320.46, *bp* 174 – 178 °C (199.95 Pa); dihydrochloride [*5892-41-1*], $C_{19}H_{34}Cl_2N_2O_2$, M_r 393.4, *mp* 174 – 178 °C; camylofin bis(noramidopyrine mesylate), $C_{45}H_{66}N_8O_{10}S_2$, M_r 943.31. For synthesis, see [61], [62].

Trade Names. Avacan (Bosnalijek, Yugoslavia; Etem, Turkey); present in Spasmo-Urolong (Thiemann, FRG).

Dicyclomine [*77-19-0*], 2-diethylaminoethyl 1-cyclohexyl-1-cyclohexanecarboxylate, dicycloverine, $C_{19}H_{35}NO_2$, M_r 309.5; hydrochloride [*67-92-5*], $C_{19}H_{36}ClNO_2$, M_r 345.94, *mp* 164 – 166 °C. Obtained by conversion of bicyclohexyl-1-carbonitrile to the ethyl ester, followed by transesterification with 2-diethylaminoethanol [63], or as described in [64], [65]. The hydrochloride is a white, almost odorless, crystalline substance, soluble to the extent of ca. 25 % in water. Dicyclomine exerts a papaverine-like and antimuscarinic effect, but is clearly weaker than atropine. This substance was introduced as a therapeutic agent in 1947, and is used in the treatment of spasms in the region of the gastrointestinal tract.

Trade Names. Atumin (Merrel, FRG), Bentyl (Lepetit, Italy; Lakeside, USA), Bentylol (Merrel Dow, Canada, Spain), Icramin (Toho Iyaku, Japan), Merbentyl (Merrel Dow, Australia, UK).

Dihexyverine [*561-77-3*], 2-piperidinoethyl 1-cyclohexyl-1-cyclohexanecarboxylate, $C_{20}H_{35}NO_2$, M_r 321.49; hydrochloride [*5588-25-0*], $C_{20}H_{36}ClNO_2$, M_r 357.96, *mp* 200 °C. For synthesis, see [66], [67].

Trade Name. Spasmodex (Crinex, France).

Diisopromine [*5966-41-6*], *N*,*N*-diisopropyl-3,3-diphenylpropylamine, $C_{21}H_{29}N$, M_r 295.45; hydrochloride [*24358-65-4*], $C_{21}H_{30}ClN$, M_r 331.91, *mp* 175 – 176 °C. For synthesis, see [68], [69]. Diisopromine is often used with sorbitol in the treatment of spasms in the region of the bile ducts, and to increase choleresis.

Trade Names. Megabyl (Janssen, France; Pharmacal, Switzerland), Polagol (Polfa, Poland).

Drofenine [*1679-76-1*], 2-diethylaminoethyl 2-cyclohexyl-2-phenylacetate, $C_{20}H_{31}NO_2$, M_r 317.48, *bp* 158 °C (19.99 Pa); hydrochloride [*548-66-3*], $C_{20}H_{32}ClNO_2$, M_r 353.94, *mp* 145 –147 °C. The cyclohexylphenylacetic acid present in drofenine as the diethylaminoethyl ester can be made from benzyl cyanide and cyclohexyl bromide or by hydrogenation of diphenylacetic acid or benzilic acid [70]. Drofenine hydrochloride is readily soluble in water, and very slightly soluble in ethanol and ether. Introduced as a therapeutic agent in 1938, drofenine is the spasmolytic component in several combination preparations.

Trade Names. Spasmo-Cibalgin S, Spasmo-Cibalgin-compositum S (Ciba Geigy, FRG).

Flavoxate [*15301-69-6*], 2-piperidinoethyl 3-methyl-4-oxo-2-phenyl-4*H*-1-benzopyran-8-carboxylate, $C_{24}H_{25}NO_4$, M_r 391.45; hydrochloride [*3717-88-2*], $C_{24}H_{26}ClNO_4$, M_r 427.91, *mp* 232 – 234 °C. For synthesis, see [71], [72]. Preparation via transesterification of flavonecarboxylate esters using tetraisopropyl titanate or bis(acetylacetonato)zinc complexes as catalysts is described in [73]. Flavoxate is used for the symptomatic relief of certain disorders of the lower urinary tract and for the relief of vesico-urethral spasms resulting from the use of instrumentation (e.g., catheters) or surgery.

Trade Names. Bradalone (Japan), Genurin (Recordati, Italy), Spasuret (Farmitalia, FRG), Urispadol (Pharmacia, Denmark, Norway); Urispas (Byk Gulden, Austria; Cedona/Byk, Belgium; Cilag, Portugal; Galenica, Switzerland; Smith Kline & French, USA; Syntex, UK).

Oxybutynin [*5633-20-5*], (±)-4-diethylamino-2-butinyl α-cyclohexyl-α-phenylglycolate, $C_{22}H_{31}NO_3$, M_r 357.49; hydrochloride [*1508-65-2*], $C_{22}H_{32}ClNO_3$, M_r 393.97, *mp* 129 – 130 °C. For syntheses, see [74], [75]. (±)-Oxybutynin is used in managing the urgency and incontinence associated with neurogenic bladder. Anticholinergic activity resides mainly in the (*R*)-enantiomer; oxybutynin displays additional nonstereoselective effects for Ca^{2+}-channel antagonism as well as spasmolytic and local anesthetic properties [46].

Trade Names. Cystrin (Leiras, Finland), Ditropan (Debat, France; Marion, USA; Scharper, Italy; Therapia, Switzerland), Dridase (Byk Gulden, the Netherlands; Pharmacia, FRG).

Pitofenone [*54063-52-4*], methyl 2-[4-(2-piperidinoethoxy)benzoyl]benzoate, $C_{22}H_{25}NO_4$, M_r 367.43, *mp* 168 – 169 °C; hydrochloride $C_{22}H_{26}ClNO_4$, M_r 403.91. The synthesis is described in [76].

Trade Name. Contained in Litalgin (Leiras, Finland).

Propiverine [*60569-19-9*], 1-methyl-4-piperidyl 2,2-diphenyl-2-propoxyacetate, $C_{23}H_{29}NO_3$, M_r 367.49; hydrochloride $C_{23}H_{30}ClNO_3$, M_r 403.99. For synthesis, see [77]. Propiverine is used mainly in the treatment of micturition problems associated with neurogenic bladder. The possible metabolite *O*-dealkylpropiverine has more than one-hundred times the affinity of propiverine for muscarinic receptors, and is more potent than atropine [78]. For further details of the pharmacology, see [79].

Trade Names. Mictonetten, Mictonorm (Apogepha Arzneim., FRG).

Terolidine [*15793-40-5*], (±)-*N*-*tert*-butyl-4,4-diphenyl-2-butylamine, $C_{20}H_{27}N$, M_r 281.44, *bp* 130 – 132 °C (133.3 Pa); hydrochloride [*7082-21-5*], $C_{20}H_{28}ClN$, M_r 317.90, *mp* 178 – 180 °C. Prepared by the reductive condensation of 4,4-diphenyl-2-butanone with *tert*-butylamine in the presence of $AlCl_3$ [80]; for an alternative synthesis, see [81]. (±)-Terolidine is used for relief of urinary frequency, urgency, and incontinence in patients with motor-urge incontinence and neurogenic bladder. The racemate displays both anticholinergic and calcium-channel blocking properties [45].

Trade Names. Mictrol (Globopharm, Switzerland; KabiVitrum: Austria, Denmark, the Netherlands, Sweden), Micturin (KabiVitrum, UK).

Thiphenamil [*82-99-5*], *S*-2-diethylaminoethyl diphenylthioacetate, tifenamil, thiphenum (USSR pharmacopoeia), $C_{20}H_{25}NOS$, M_r 327.50; hydrochloride [*548-68-5*], $C_{20}H_{26}ClNOS$, M_r 363.96, *mp* 129 – 130 °C. For synthesis, see [82]. Thioesters like thiphenamil and its *N*,*N*-dimethyl or *N*,*N*-dipropyl derivatives [83], [84] are pharmacologically similar to the corresponding oxygen compounds, and are used primarily in Eastern Europe.

Trade Name. Trocinate (Poythress, USA).

4. Miscellaneous Agents

In certain special cases, substances may be employed which are ordinarily indicated for other conditions (e.g., hypertension, coronary insufficiency, or bronchial asthma). For example, α- or α_1-adrenoceptor antagonists, such as phentolamine [*50-60-2*], phenoxybenzamine [*59-96-1*], or prazosin [*19216-56-9*], are effective in ureteral-stone colic, ureteral spasms, and conditions involving increased α-adrenergic tone of the sphincter of the urinary bladder. The β_2-adrenoceptor agonists used in asthma therapy (e.g., fenoterol [*13392-18-2*]) are employed to relax the uterus in premature labor (tocolytic agents). Organic nitrates, such as glycerol trinitrate [*55-63-0*], useful in coronary heart disease, cause relaxation not only of the vascular smooth muscle, but also of the bronchial smooth muscle and smooth muscle of the gallbladder and bile ducts. There-

fore, glycerol trinitrate is occasionally administered by infusion in the treatment of gall-stone colic and lead colic. Indomethacin [*53-86-1*] and other inhibitors of prostaglandin biosynthesis (nonsteroidal antiphlogistics, → Anti-inflammatory – Antirheumatic Drugs, Chap. 3.) are used in the treatment of spasmodic dysmenorrhea. For additional information on the mechanisms of drug action see → Pharmaceuticals, General Survey and Development.

5. Future Prospects

The discovery of the heterogeneity of the muscarinic receptors and the pharmacological, biochemical, and molecular-biological characterization and localization of five receptor subtypes has opened new perspectives for specific therapeutic influence on muscarinic receptor-mediated functions. Spasms of smooth muscle may be subject to more effective treatment, and with fewer side effects, with highly selective M_3 antagonists. The first prototype substance is represented by *p*-fluorohexahydrosiladifenidol [85–87], a (relatively) M_3-selective antagonist used in experimental pharmacology. A new class of potentially selective M_3 antagonists has been described [88]. Compounds of the newly developed group of potassium- channel openers [89], [90], such as cromakalim [*94470-67-4*] and pinacidil [*60560-33-0*], also exert relaxing effects on smooth muscles. Certain substances in this group are already in clinical trials as antihypertonic and antiasthmatic agents. Nonpeptidic tachykinin-receptor antagonists [91] represent another potential source of new spasmolytic agents.

1. Introduction

In this article, "specialty plastics" are defined as those plastics which do not fit into other keywords, either because they are prepared from unusual monomers or because they possess unique structures and/or properties. However, the term "specialty plastics" is in general often used as a synonym for "high-performance plastics", which are a special class of engineering plastics (technical plastics, technoplastics; see → Plastics, General Survey, Chap. 1.2.1.). Engineering plastics provide the engineer with a combination of useful properties, whereas high-performance plastics often exhibit only one outstanding property albeit one which surpasses the corresponding property of engineering plastics, e.g., a high continuous service temperature.

"Specialty plastics" are also not necessarily identical with either "functional plastics" or "functional polymers." Functional plastics are those plastics which are useful for one application only; examples are ethylene – vinyl alcohol copolymers with high contents of vinyl alcohol units, which are exclusively used as gas and aroma barriers in the packaging industry. The term "functional polymer" or "functionalized polymer", on the other hand, refers to polymers with functional chemical groups, i.e., specific chemical reactivities.

The polyphenylenes and poly(*p*-xylylenes) described in this article are typical functional plastics since they are used for only one purpose: coatings. The group of polymers known as ionomers, on the other hand, comprises functional plastics, engineering plastics, elastomers, and thermoplastic elastomers.

2. Polyphenylenes

2.1. Chemical Structure

Polyphenylenes are oligomeric to polymeric compounds composed of phenylene units and related units such as naphthalene or anthracene; these units are connected to each other via *ortho*, *meta*, and/or *para* links. Their molecular architecture thus ranges from linear to

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_529

highly branched compounds; they may or may not become cross-linked on further processing. Polyphenylenes are also known as polyphenyls, oligophenyls, oligophenylenes, or polybenzenes [1–7].

Polyphenylenes exhibit two remarkable properties. As compounds of low hydrogen content and free of readily activated chemical bonds, they show good thermal, oxidative, and hydrolytical stability. As aromatic compounds, they have the potential of becoming electrically conducting materials. Commercial developments are thus along two lines: polyphenylenes are either prepared as thermosetting resins with high service temperatures or as base materials for electrically conducting polymers.

The two classes of polyphenylenes differ in their chemical structures. Polyphenylenes for conductors are linear polymers with phenylene units interconnected in 1,4-position (PPP [*25190-62-9*]), whereas polyphenylenes for thermosets are highly branched oligomers [*9033-83-4*], often with reactive end groups such as acetylene (schematically shown as PXP). This section is exclusively concerned with the latter type of polymers; poly(1,4-phenylenes) are discussed in → Polymers, Electrically Conducting, Chap. 5.5.

PPP

PXP

2.2. Polybenzenes

Melting temperatures of simple poly(1,4-phenylenes) increase strongly from biphenyl $H(C_6H_4)_2H$ (70 °C) to hepta(1,4-phenylene) $H(p\text{-}C_6H_4)_7H$ (ca. 540 °C). Poly(1,4-phenylenes) were thus expected to be very temperature stable compounds. All classic stepwise syntheses of such polyphenylenes are, however, too expensive for the industrial manufacture of plastics but may be utilized for electrically conducting polymers [1], [2], [6], [7].

The first industrial branched polyphenylenes were prepared by oxidative cationic polymerization of benzene with stoichiometric amounts of aluminum trichloride/copper dichloride, iron trichloride, molybdenum pentachloride, etc. [3–5], [8–10]. The arylation reaction proceeds via radical cations [7], [11]. The polymers still contain 1 – 4 % chlorine, < 5 % oxygen, 0.1 – 0.2 % copper, and 0.3 – 0.6 % aluminum after purification [5].

The resulting brown to black masses have densities of ca. 1.25 g/cm^3, tensile strengths of 65 MPa, Young's moduli of 160 MPa, elongations at break of 10 %, and linear expansion coefficients of ca. 3×10^{-5} K^{-1}. They melt above 530 °C and decompose above 700 °C. Their melt viscosities are so high that they cannot be processed by injection molding or similar fabrication techniques. The polymers can, however, be molded at high pressure; the moldings can then be machined. Such materials are produced as Eimac 221 by Eitel – McCollough, United States.

2.3. Polymers from Higher Aromatic Hydrocarbons

The oxidative cationic polymerization of terphenyl isomers, with or without addition of other compounds such as biphenyl, reduces the probability of cross-linking reactions as compared to benzene. The resulting branched prepolymers are soluble; their solutions in chloroform or chlorobenzene are used as impregnating varnish for laminates. Filled prepolymers can be processed in the melt. The prepolymers are cross-linked to give insoluble and unmeltable polymers by the addition of catalysts such as *p*-toluenesulfonic acid, sulfuryl chloride, or boron trifluoride etherate. These techniques are mainly being developed by Hughes Aircraft Co.

2.4. Acetylene Group Containing Polymers

Other types of branched polyphenylenes are the so-called H-resins of Hercules [12–15]. These

prepolymers are obtained by cyclotrimerization of *p*-diethynylbenzene (DEB) in aromatic solvents [16] or by copolycyclotrimerization of DEB with phenylacetylene [17]; catalysts are $AlR_3/TiCl_4$, $NiCl_2/P(C_6H_5)_3/NaBH_4$, or $CoBr_2/(C_6H_5O)_3P$.

The prepolymers (B-stage resins) are oligophenylenes with the schematic structure PXP (see Section 2.1). For B-stage resins from the polymerization of DEB by $TiCl_4/(C_2H_5)_2AlCl$ at 86 % monomer conversion, a number-average molar mass of 2300 g/mol and a mass-average molar mass of 8060 g/mol were found. Higher DEB conversions resulted in gelation.

These polymers contain acetylene end groups that form cross-links under the action of titanium(IV) chloride/diethylaluminum chloride, nickel(I) acetylacetonate, and similar catalysts. The chemical structure of these cross-links is unknown; they are probably not benzene rings.

B-Stage H-resins dissolve in aromatic hydrocarbons, chlorinated hydrocarbons, ketones, and cyclic ethers. They are insoluble in water, aliphatic hydrocarbons, and aliphatic alcohols. The resins can be processed with simultaneous cross-linking by molding, injection molding, extrusion, and powder coating; different grades are provided for these purposes. Molding cycles are 2 – 5 min at 160 – 170 °C [13]. Molding stability starts at 160 °C but improved mechanical stabilities and better solvent resistance require postcuring at 230 – 300 °C.

The cured resins are hard, nonporous materials which are resistant to hot solvents, acids, bases, brine, superheated steam, and salt melts. They become brittle in molten alkali metals. Continuous service temperatures are 200 – 300 °C in air and ca. 400 °C in an oxygen-free atmosphere; the limiting oxygen index is 55 %. Slow carbonization starts at ca. 500 °C.

Molded parts show flexural moduli of several gigapascal and high flexural strengths (Table 1). These properties can be enhanced by fillers such as talc, silica, or asbestos. They are often preserved over a wide temperature range.

Unmodified H-resins exhibit low elongation and low adhesion to polar substrates. The adhesion of H-resins to metal surfaces can be improved by the use of polymer blends and polymeric fillers such as epoxy resins, phenolic resins, polysulfones, and polyimides.

H-Resins serve as corrosion-resistant coatings, for example, for pipes and processing equipment for hot sour petroleum or gas wells, pump linings, high-temperature sodium and lithium batteries, and high-temperature processing equipment. They are also used as nonflammable coatings for electric and electronic components and as self-lubricating coatings for metals.

3. Poly(*p*-Xylylenes)

3.1. Introduction

Poly(*p*-xylylenes), PPX, are polymers of the unstable *p*-xylylenes (*p*-quinodimethanes) PX; they are produced industrially from the dimeric *p*-xylylenes DPX:

The syntheses, structures, and properties of PPX are described in [18–25]. Although PPXs with many different substituents R, R^1, R^2, and R^3 have been prepared in the laboratory (see the list in [23]), only three of them are industrially important. These polymers are based on DPX as monomer and have no (N) or one chlorine (C) substituent, or are disubstituted (D) with chlorine:

PPX-N ($R = R^1 = R^2 = R^3 = H$) [*25722-33-2*]
PPX-C ($R = R^2 = R^3 = H$; $R^1 = Cl$) [*9052-19-1*]
PPX-D ($R = R^3 = H$; $R^1 = R^2 = Cl$) [*52261-45-7*]
The systematic names are:

Table 1. Properties of cured H-resins

Physical property	Temperature, °C	Property value after filling with		
		none	50 wt % talcum	50 wt % silica

	250		<62	62
	350	<55	<55	46
Barco hardness	23	85		
Taber abrasion (17) (1000 g load)	23	0.0015		
Volume resistivity, Ω cm	23	10^{17}		
Dissipation factor (60 Hz)	23	0.002		
	100	0.0009		

PPX-N	poly(1,4-phenylene-1,2-ethanediyl)
PPX-C	poly[(chloro-1,4-phenylene)-1,2-ethanediyl]
PPX-D	poly[(dichloro-1,4-phenylene)-1,2-ethanediyl]

The designations monochloro and dichloro PPX for technical products are misleading since these polymers do not have one or two chlorine substituents on each ring. Monochloro and dichloro rather refer to the average number of chlorine ligands per ring, i.e., there is a distribution of chlorine substituents amongst the rings; each ring in PPX-C or PPX-D may bear between 0 and 4 chlorine substituents.

Poly(*p*-xylylenes) from the Gorham process (see below) are known as parylenes. Coatings produced by this process are correspondingly named parylene N, parylene C, and parylene D. The sole producer of dimeric *p*-xylylenes DPX-N, DPX-C, and DPX-D is Union Carbide, which also custom-coats parts with PPX-N, PPX-C, and PPX-D.

3.2. Synthesis

3.2.1. Monomer Synthesis

Two synthetic routes have been used commercially for the synthesis of dimeric *p*-xylylenes DPX, also known as [2.2]-paracyclophanes: direct pyrolysis and Hofmann elimination. In direct pyrolysis, *p*-xylene X is pyrolyzed at ca. 950 °C in the presence of steam. The pyrolysis dehydrogenates *p*-xylene X to *p*-xylylene PX-N which is converted into di-*p*-xylylene DPX-N on quenching with liquid xylene at ca. 20 °C:

A major byproduct is the polymer PPX-N. Its simultaneous formation can be minimized by using an excess of liquid xylene (Ruggli – Ziegler dilution principle), controlled rates, etc. The polymeric byproduct has no commercial value since it can be neither processed nor recycled.

The Hofmann elimination proceeds under far milder conditions and does not need special equipment, unlike the direct pyrolysis. α-Bromo-*p*-xylene is first quaternized and the resulting product converted into the quaternary ammonium hydroxide; amine elimination then leads to DPX-N:

The yields of DPX-N vary between 17 and 50 %, depending on the reaction conditions (e.g., use of polymerization inhibitors).

Chlorine-containing dimeric *p*-xylylenes are produced industrially by chlorination of DPX-N using standard procedures for aromatic ring chlorinations. Chlorination gives mixtures of unreacted DPX-N with various chlorinated compounds (from mono to tetra substitution per ring) and their isomers.

3.2.2. Polymerization

Poly(*p*-xylylenes) can be synthesized by the Szwarc or the Gorham process. In the Szwarc process [26–28], *p*-xylene vapor is passed rapidly (residence time < 1 s) in vacuum (< 100 Pa) through quartz tubes heated to 800 – 1150 °C. The pyrolysis gases are subsequently quenched to temperatures below 25 °C. The mechanism was assumed [26–28] and later confirmed [29–32] to consist of the formation of monoradicals (either spontaneously or by radical transfer), followed by disproportionation to give *p*-xylylene, and finally polycombination of the diradicals to give poly(*p*-xylylene):

The diradical and not the *p*-xylylene is the intermediate species since the former is stable in the gas phase between 120 °C and 200 °C and in liquid phases (such as quenched hexane solutions) at low temperatures (half-life 21 h at −78 °C). The resulting poly(*p*-xylylene) is slightly cross-linked; it always contains 10 – 25 wt % of low molar mass impurities. Furthermore, since the yield never exceeds 25 %, the process was technically and economically useless.

The Gorham process, on the other hand, leads to colorless, linear (uncross-linked) polymers that are free of low molar mass compounds [33], [34]. The process uses di-*p*-xylylene DPX as monomer and proceeds in three stages: (1) DPX is vaporized at ca. 200 °C and 133 Pa, (2) on heating to 680 °C at ca. 67 Pa, DPX dissociates quantitatively [21] to *p*-xylene which, after cooling to 25 °C and 13 Pa, (3) polymerizes to poly(*p*-xylylene) PPX on the surfaces of parts in a deposition chamber at < -70 °C:

p-Xylylene PX can be represented by quinoid (diamagnetic) or benzoid (paramagnetic) structures. The vapor of PX is diamagnetic [24].

The polymerization is thus probably started by paramagnetic diradical structures; such species may be the dimeric diradical from a one-sided ring-opening of DPX-N, the benzoid structure of PX, or the dimeric diradical from the coupling of two *p*-xylylene molecules. The polymerization seems to be propagated by addition of the diamagnetic quinoid structures to the growing macrodiradicals and not (or only slightly) by the polyrecombination of macrodiradicals. The polymerization proceeds as living polymerization with radical concentrations of $(5-10)\times 10^{-4}$ mol of free radicals per mole of xylene units of the final polymers.

Polymer yields are 100 % at −50 °C and drop rapidly at temperatures above ca. 0 °C (Fig. 1). Molar masses are almost independent of polymerization temperature in the range −50 °C to +50 °C [35].

The Gorham process can be applied to substituted [2.2]-paracyclophanes, provided the threshold condensation temperatures for the condensation on surfaces are not exceeded. These threshold temperatures are 30 °C for poly(*p*-xylylene), 60 °C for poly(2-methyl-*p*-xylylene), 90 °C for poly(2-chloro-*p*-xylylene),

Figure 1. Dependence of polymer yield γ and reduced viscosity η_{red} (1×10^{-3} g/mL polymer in α-chloronaphthalene at 238 °C) of poly(*p*-xylylenes) on the polymerization temperature T_p (data from [35])

and 130 °C for poly(2,5-dichloro-*p*-xylylene) [34]. The physical meaning (other than the phenomenological) of the threshold temperature is unclear since the most obvious interpretation as thermodynamic ceiling temperatures is made difficult by reports of very high estimated thermodynamic ceiling temperatures of more than 200 °C for a gas pressure of 0.08 torr (11 Pa) [35] and calculated ceiling temperatures of 1149 °C (gas) and 3035 °C (liquid) for PX [25]. However, such calculations suffer from the absence of knowledge about the true nature of the polymerization: true equilibria between all species (monomers, monomeric diradicals, macrodiradicals), equilibria between monomers and macrodiradicals only, or even kinetically-controlled reactions.

Poly(*p*-xylylenes) can also be obtained by other methods [25], [36], [37], none of which seem to be used industrially since the monomers are too expensive and/or the polymers are obtained in low yield, with low molar masses, or with many low molar mass impurities.

3.3. Structure

Chemical Structure. Poly(*p*-xylylenes) from the Gorham process are linear polymers, whereas those from the Szwarc process are slightly cross-linked. The number-average molar mass, as calculated from the free-electron concentration of living PPX-N polymers [33], is ca. 200 000 – 400 000 g/mol. Osmometry of soluble fractions in chloroform gave 24 000 g/mol [24].

The commercial chlorinated monomers DPX-C and DPX-D are complex mixtures with 0 – 8 chlorine groups per molecule and 0 – 4 chlorine substituents per ring. On pyrolysis and subsequent vapor deposition polymerization, DPX-C with an average of one chlorine substituent per ring thus gives mainly base units $-CH_2-(p-C_6H_3Cl)-CH_2-$ besides considerable amounts of base units $-CH_2-(p-C_6H_4)-CH_2-$ and $-CH_2-(p-C_6H_2Cl_2)-CH_2-$. Chlorinated units may be arranged head-to-head, head-to-tail, and tail-to-tail so that the resulting constitutional copolymers also show regio-isomerism.

Physical Structure. PPX-N has two crystal modifications [38], [39]. The monoclinic α-modification is formed between −17 °C and +30 °C, while the triclinic β-modification exists below −78 °C and above 220 – 260 °C. The unit cell of the α-modification consists of two monomer units. The phenylene units are parallel to each other; the angle between the plane of the benzene rings and the methylene chain is 90°.

The $\alpha \rightarrow \beta$ transition at 220 °C is accompanied by a marked increase in brittleness. At 270 °C, a reversible smectic transition is observed.

Vapor deposition polymerization is carried out below the melting and near the glass temperatures of the polymers (see Table 2); any crystallization must thus occur simultaneously with the polymerization on surfaces. At polymerization temperatures between 0 °C and 60 °C, the α-modification is formed, whereas mixtures of α and β are found for polymerization temperatures above 80 °C.

The degree of crystallinity of parylene N has been reported to be 57 % [25]. The density of amorphous PPX-N, as calculated from the experimental density of 1.11 g/cm^3 and the theoretical density of the α-modification of 1.185 g/cm^3 (from the unit cell), is thus 1.070 g/cm^3.

3.4. Manufacture

Parylenes are exclusively prepared and applied by vapor deposition polymerization of DPXs on surfaces (Gorham process). Total production is estimated to be several tonnes per year.

Film formation by vapor deposition polymerization differs from other coating techniques in that the coating is formed from the gaseous phase rather than from a liquid one (no surface tension effects on wetting) and that the film grows from the substrate upwards and not downwards as in drying films. The films are self-adherent; coupling agents are usually not necessary.

The technique produces pinhole-free coatings of uniform thickness even on complex, three-dimensional substrates with hidden areas. Films have thicknesses between 0.050 and 100 µm. They are flexible even at low temperatures and possess good dimensional stability.

These features, together with good electrical and mechanical properties and low gas and water vapor permeability, make parylenes especially suitable for surface coating of electrical and electronic components such as printed and integrated circuits, capacitors, transistors, and miniature electrical components. Parylenes are also applied for particle encapsulations, thin membranes, lubricants, and long-term implantation devices.

3.5. Properties

Properties of poly(*p*-xylylenes) are listed in Table 2.

Solubility. Poly(*p*-xylylenes) from the Gorham process are sparingly soluble. PPX-N dissolves to 1.5 % and PPX-C to 10 % in methylene chloride at 25 °C [25]. The solubility of PPX-N in xylene is ca. 10 % at 140 °C. PPX-N and PPX-D can be dissolved in chlorinated biphenyls or in benzyl benzoate at temperatures above 200 °C, and PPX-C in 1-chloronaphthalene at 150 °C [33]. Cooling the solutions to below 150 – 200 °C leads to gel-like precipitation of the polymer. Repeated dissolution and precipitation cause degradation.

Aromatic and halogenated aromatic compounds swell parylenes at room temperature, but stress corrosion has not been observed. Parylenes are resistant to concentrated sulfuric acid and 5N nitric acid.

Thermal Properties. Melting temperatures of symmetrically substituted poly(*p*-xylylenes) PPX-N and PPX-D are higher than those of unsymmetrically substituted PPX-C. The glass temperature of PPX-N is fairly low (T_g = 13 °C) [25], and lower than the earlier reported 80 °C [21]. Similar low glass temperatures can be expected for PPX-C and PPX-D; earlier reported glass temperatures of 80 – 110 °C are definitely too high since no sudden upswing of relative permittivity (dielectric constant) ε_r due to the onset of segmental motions is observed in the temperature interval 20 – 190 °C, only a continuous increase of ε_r from 3.0 to 4.7.

Since the glass temperature is lower than ambient temperature, structural changes occur upon aging and/or annealing of parylenes; freshly deposited polymers have other properties than old ones.

The stability of parylenes is determined by the dibenzyl groups, which are easily oxidized and thermally cleaved. The continuous service temperature of PPX-N is thus only 100 °C in air and 220 °C under an inert atmosphere (see Table 2).

Table 2. Properties of poly(*p*-xylylenes) [25], [34], [40], [41]

Property	Property values of

H_2O	428	150	

Mechanical Properties. Parylenes have tensile strengths and elastic moduli (Table 2) similar to those of other engineering plastics. The unusually high elongation at break of PPX-C refers to freshly deposited films; such films have high dimensional stability if subjected to high relative humidities. Films remain tough and flexible down to −165 °C. Since further crystallization takes place on annealing, density, hardness, and abrasion resistance also increase.

Permeability. Gas permeabilities (O_2, N_2) of parylenes are similar to those of poly(ethylene terephthalate), and water vapor permeabilities compare favorably with those of high-density polyethylene. PPX-C and PPX-D have also low permeability for SO_2 and H_2S.

Electrical Properties. Parylenes from the Gorham process have low relative permittivity (dielectric constant) and dielectric loss (dissipation factor) due to their chemical structures (only carbon and hydrogen, no hydrophilicity, no dipoles) and the absence of low molar mass impurities and catalyst residues. Dielectric strengths are high compared to other polymers, which is in part due to the thinness of the test films (0.025 mm) since dielectric strengths

decrease with increasing thickness and dielectric strengths of other polymers are usually measured at thicknesses of 3.18 mm.

4. Polybenzocyclobutenes

Polybenzocyclobutenes are polymers and copolymers of various benzocyclobutenes [42–46]. On heating, the parent compound, benzocyclobutene (BCB), is converted to the unstable *o*-quinodimethane, OQDM (*o*-xylylene, OX), which polymerizes thermally to polybenzocyclobutene (PBCB):

BCB [*694-87-1*] OQDM, OX PBCB (**1**) [*51774-83-5*]

The intermediate is not a biradical but has an *o*-quinone structure (ground-state singlet) according to theoretical calculations. This intermediate is the true monomer; the polymer can thus also be called a poly(*o*-quinodimethane) or a poly(*o*-xylylene).

Syntheses of benzocyclobutene derivatives start with either benzocyclobutene or 3-bromobenzocyclobutene. Monobenzocyclobutenes (functionality 2) such as **2** lead to linear polymers, and bis(benzocyclobutenes) (functionality4) such as **3–7** to cross-linked polymers.

The polymerization proceeds without formation of volatile products. It does not require catalysts or initiators and it is first order in benzocyclobutene groups. The polymerization temperature of BCB is 200 – 250 °C; it is lower for substituted benzocyclobutenes **2–7**, regardless of whether the groups are electron donating or electron withdrawing.

The polymerization mechanism of the bis-benzocyclobutene monomers **3–7** is not known with certainty: intermolecular reactions **1** may either lead to random cross-linking or to ladder-type structures.

All polymers of **2–7** have high thermal stability. The good mechanical properties (Table 3) are retained at temperatures up to 200 – 250 °C.

5. Ionomers and Related Polymers

5.1. Overview

5.1.1. Introduction

Terms such as ion-containing polymer, ionic polymer, ionomer, polyelectrolyte, etc., are commonly used in polymer literature. None of these terms are defined by international standardization bodies and their meaning often differs from similar ones in other branches of science.

The term "ion-containing polymer" in its literal sense does not specify whether ions are part of the polymer molecules or whether they are extraneous to the polymer molecules, for example,

Table 3. Physical properties of polymers from a benzocyclobutene 2 and various bisbenzocyclobutenes 3 – 7

Property	Property values of polymer

catalyst residues or other impurities. In the polymer literature, the term "ion-containing polymer" is used as a shorthand notation for "ion-containing polymer molecules"; i.e., it refers exclusively to ionic structures attached to polymer molecules.

Polymer molecules with ionic structures are often called ionic polymers. They are usually subdivided into two groups [47]: water-soluble and water-insoluble. Water solubility is commonly shown by polymer molecules with high contents of ionic groups; these polymers are called polyelectrolytes (Section 5.1.2). Polyelectrolytes may, for example, contain basic groups such as $-NH_2$ or acidic groups such as $-COOH$.

The terminology is less clear for water-insoluble polymers with small contents of ionic groups. If these groups are acid groups such as $-COOH$ or $-SO_3H$, the polymers are termed acidic but never ionic. The term "ionic" is reserved here for polymers with small proportions of salt groups such as $-COONH_4$, $-COONa$, or $(-SO_3)_2Zn$. The designation of these polymers as "ionic polymers" is furthermore not meant to imply that the ionic structures are indeed present as ions, i.e., with charge separation (Section 5.1.3).

The incorporation of small amounts of acidic and/or ionic groups into apolar backbone chains causes these groups to associate ("aggregate") in the solid state. The resulting intermolecular physical cross-links lead to higher moduli and strengths. The cross-links dissociate at higher temperatures and the polymers can then be processed conventionally.

5.1.2. Polyelectrolytes

The ionic groups of polyelectrolytes may be in side chains as in **8** and **9** or in backbones as in **10–12**:

Polyelectrolytes may be polyacids such as poly(acrylic acid) **8** and poly(phosphoric acid) **10**, or polybases such as poly(vinyl amine) **9** and poly(ethylene imine) **11**. In water and other highly polar solvents, they dissociate into polyions and oppositely charged counterions. Upon dissociation, polyacids lose protons and become polyanions (e.g., $\sim[CH_2-CH(COO^-)]_n\sim$). The salts of these polyanions are thus called polysalts (e.g., $\sim[CH_2-CH(COO^-Na^+)]_n\sim$). Polybases can quaternize by adding protons, methyl groups, etc., and become polycations; the quaternization may be in the substituent as in **9** or in the main chain as in **11**. Polymers which only exist as polycations but not as polybases are called ionenes, an example of which is **12**, the polymer of 4-vinylpyridine by polymerization via the 1,6-positions.

Polyacids, polybases, polyanions, and polycations contain many acidic, basic, anionic, and cationic groups per molecule. They are to be distinguished from macroacids, macrobases, macroanions, and macrocations, which have only one such group (as in, e.g., living anionic polymerizations with monofunctional initiators), and from macrodiacids, etc., with two such functional groups, etc.

Polyampholytes are polymers whose chains carry both acidic and basic (or anionic and cationic) groups; an example is the copolymer of acrylic acid $CH_2{=}CHCOOH$ and acrylamide $CH_2{=}CHCONH_2$. Complexes of polyacids and polybases are called polyelectrolyte complexes or symplexes; they may or may not be water soluble, depending on their chemical structure (see also [47]).

5.1.3. States of Ions

In science "ion" denotes an electrically charged atom or molecule (cation or anion) which shows ionic conductivity as a free entity (in solution or as gas) or in its assemblies (in crystals or melts). Each ion possesses an oppositely charged counterion due to the principle of electroneutrality; the electric charges are separated. In polymer science, "ion-containing" does not necessarily refer to charge-separated entities, especially not in the solid state; it is merely necessary that these entities may be able to generate ions under favorable (polar) conditions.

Under less polar conditions, ions can form ion pairs consisting of oppositely charged ions bound together by Coulomb interactions but not by covalent bonds. In contact ion pairs, these ions are in direct contact. In the presence of polar solvents, the ions may be also more loosely held together in solvent-separated ion pairs; such ion pairs may share one solvent molecule or two or more.

Triple ions arising from Coulombic interactions such as $\sim\sim COO^-/M^{2+}/^-OOC\sim\sim$ from two carboxylate groups $\sim\sim COO^-$ and a metal ion M^{2+} are especially stable ionic structures since the sum of the repulsion between two anions and the attraction between the cation and two anions results in a negative potential energy [48]. The same reasoning applies to higher ion aggregates; such structures are responsible for the stability of ion crystals such as NaCl. Triple ions are sometimes called triplets although the latter term should refer exclusively to multiplets of ion pairs.

Ion pairs can associate to form tightly aggregated ion multiplets consisting of associated ion pairs (2 ion pairs), triplets (3 ion pairs), etc.:

The maximum number of ion pairs in such multiplets should be six to eight if the multiplets are spherical. Ion multiplets do not contain polymer chain segments; sizes of spherical multiplets cannot exceed ca. 0.6 nm because of geometrical constraints on the multiplet structures by the chain segments to which the multiplets are attached. Because of their small size, they are not separate phases in solid polymers; they thus directly affect matrix properties such as segment mobilities. No size restriction is imposed on nonspherical geometries.

Multiplets may aggregate into ion clusters [49] which contain significant amounts of polymer segments in addition to the ionic structures [50], [51] (for a review of these and other theories, see [52]). The domains of these clusters are thus considerably larger than those of multiplets; their size is limited to 2 – 10 nm by the elastic forces generated by the backbone chains. These clusters approach the size of true phases. Clusters thus do not markedly affect matrix properties except that they may behave as cross-links with reinforcing action.

Free ions and solvent-separated ion pairs conduct electricity, but contact ion pairs, contact multiplets, and ion clusters do not. Most ion-containing polymers are electrical insulators

in the solid state; since obviously no ions are present, they really should not be called ion-containing polymers.

5.2. Acidic Copolymers

5.2.1. Introduction

Acidic copolymers are defined as copolymers of a parent monomer (or several thereof) and a small amount of an acidic comonomer. The polymers may be thermoplastic or elastomeric, depending on the glass transition temperature of the parent monomer segments.

The first acidic elastomers were copolymers of butadiene with small amounts of various unsaturated acids, patented by I. G. Farbenindustrie in 1930 [53]. In 1950, B. F. Goodrich started to introduce a series of acidic elastomers from butadiene, acrylonitrile, and small amounts of acrylic acid [54], [55]; the trade name Hycar now refers to polymers of different compositions and grades with many different CAS numbers. These and other acidic elastomers are also known as carboxylated elastomers or carboxylated rubbers; they are produced by many companies [56].

Hycar rubbers can be neutralized with zinc oxide or zinc salts; these neutralized acidic polymers were the first elastomeric ionomers. However, the ionomeric structures served only as reinforcing entities since the rubbers were still conventionally vulcanized to covalently cross-linked elastomers.

Neutralization of suitable acidic copolymers without chemical cross-linking leads to thermoplastic elastomers. The first thermoplastic elastomers were the cured Hypalon polymers of Du Pont. Hypalons are based on sulfochlorination of polyethylenes [57] and are available in many grades. The curing of these polymers by metal compounds leads to ionomers which behave as thermoplastic elastomers.

In the mid-1960s Du Pont began production of the first thermoplastic acidic copolymers from ethylene (E) with small amounts of methacrylic acid (MAA). These copolymers were not commercially available but were converted in-house to ionomers (Section 5.3.6).

Thermoplastic acidic EAA copolymers of ethylene (E) and up to 15 wt % acrylic acid (AA) were first commercially manufactured in various grades by Dow Chemical and Union Carbide (Section 5.2.3). They were followed by Du Pont's E-MAA copolymers with up to 15 mol % MAA (Nucrel).

Du Pont also manufactures a 1 : 1 copolymer of ethylene and methyl acrylate with small amounts of (meth) acrylic acid (Vamac) (Section 5.2.4).

Figure 2. Tensile modulus E, yield strength σ_Y, tensile fracture strength σ_B, and elongation at break ε_B of ethylene – methacrylic acid copolymers (○) and their sodium salts (▲) (100 % neutralization) as function of the mole fraction x_{MAA} of methacrylic acid units (experimental data from [58])

5.2.2. Structure and Properties

Acidic copolymers can be amorphous or partially crystalline, depending on the crystallizability of the segments of the parent monomer units. The crystalline domains are composed of lamellae formed by folded chains of parent segments and do not contain acidic units, the latter being confined to the amorphous regions where they may be present as dimers. Associated acidic units do not form separate phases. Acidic copolymers are thus one-phase materials

if amorphous, and two-phase polymers if crystalline.

Properties of such polymers depend on intramolecular and intermolecular interactions between their segments and groups. COOH groups in polyethylene segments tend to associate; the associated groups act as cross-links. At low COOH content, this association can hardly take place since the COOH groups are not free but bound to polyethylene; the geometrical constraints imposed upon the groups reduce the probability of association. Since the crystallinity of the polymer is not markedly affected, Young's moduli of ethylene – methacrylic acid copolymers remain constant up to 4 – 5 mol % of methacryclic acid groups. At higher COOH group concentrations, intermolecular association is increasingly possible. Intermolecularly associated groups act as cross-links and the moduli and yield strengths increase sharply (Fig. 2).

Polyethylene yields easily and exhibits stress-softening. The increasing association of COOH groups impedes the flow of segments, and the elongation at breaks decreases. Tensile fracture strengths of ethylene – methacrylic acid copolymers increase with increasing COOH content, eventually becoming independent of the proportion of COOH groups.

5.2.3. Thermoplastic Acidic Copolymers

Syntheses. EAA copolymers of ethylene (E) and up to 15 wt % acrylic acid (AA) are produced by Dow Chemical and Union Carbide in various grades. Du Pont manufactures an EMAA copolymer of ethylene and <15 mol % methacrylic acid MAA (Nucrel [59]) and an 1: 1 EMA copolymer of ethylene and methyl acrylate (MA) with small amounts of (meth)acrylic acid (Table 4).

None of the industrial polymerization processes have been disclosed. They are most likely high-pressure free-radical polymerizations. Since the *Q, e* values of ethylene ($Q_E = 0.015$; $e_E = -0.200$) and methacrylic acid ($Q_{MAA} = 2.34$; $e_{MAA} = 0.65$) are unfavorable for random arrangements of comonomeric units, copolymerizations are probably limited to ca. 10 % conversion in order to prevent the formation of long blocks of methacrylic acid units. Calculation of copolymerization parameters r from $r_i = (Q_i/Q_j) \cdot \exp[-e_i(e_i - e_j)]$ gives $r_{MAA} = 2.07$ and $r_E = 0.234$ and thus number-average sequence lengths $N_{MAA} = 1 + r_{MAA}$ ([MAA] / [E]) of methacrylic acid units of only $N_{MAA} \approx 1.23$ if the monomer ratio is $[MAA]/[E] = 90/10$. *Q,e* values of acrylic acid or copolymerization parameters of the ethylene – acrylic acid system have not been published but they should be similarly unfavorable.

Structure and Properties. High-pressure radical polymerization of ethylene leads to polyethylenes with a few short and long branches. The more or less random distribution of fairly bulky acid or salt units along the chains reduces the chain lengths of crystallizable segments of such polyethylenes. Melting temperatures thus decrease with increasing size of the substituents, e.g., for ethylene polymers with ca. 3 mol % comonomer units from 115 °C (LDPE with no comonomer units) to 104 °C (ethylene – acrylic acid), 95 °C (ethylene – sodium acrylate), and 90 °C (ethylene – methyl acrylate). Since the physical cross-linking caused by such comonomer units shortens the segments between cross-links, glass transition temperatures increase from −80 °C (LDPE) to −35 °C (ethylene – methyl acrylate), 0 °C (ethylene – acrylic acid), and 50 – 60 °C (ethylene – sodium acrylate).

The density of EAA copolymers increases linearily with the content of acryl acid units AA, reaching 0.95 g/cm^3 at 15 wt % AA units. Tensile yield strengths first decrease with increasing AA content, pass through a minimum at 12 – 15 wt % AA units, and increase again. The fracture strength exhibits a maximum at approximately the same AA content. Elongations at break are ca. 600 %.

Ethylene – acid copolymers show outstanding toughness since incorporated acrylic acid units reduce the formation of spherulites by polyethylene segments and simultaneously promote intermolecular association. Toughness is maintained at low temperatures; the brittleness temperature is ca. −70 °C for polymers with ca. 3 – 9 wt % acid units.

Ethylene acid copolymers show excellent adhesion to metals, glass, and paper due to the polar COOH groups and the low melt viscosities of the polymers. They also adhere well to polyeth-

Table 4. Industrial copolymers of ethylene and (meth)-acrylic acid

Parent monomers	Comonomers	Trade name	Manufacturer
Ethylene	acrylic acid	EAA 469	Dow Chemical
Ethylene	acrylic acid		Union Carbide
Ethylene	methacrylic acid	Nucrel	Du Pont
Ethylene + methyl acrylate	(meth)acrylic acid	Vamac	Du Pont

ylene because of their polyethylene segments. Adhesion to other plastics can be improved by oxidation of EAA and EMAA surfaces.

Processing. EAA and EMAA can be processed similarly to LDPE. Since the acid groups are somewhat corrosive to metals, corrosion-resistant metals or nickel or chromium plating are recommended for processing equipment.

Certain ethylene acid copolymer grades can be dispersed in hot aqueous ammonia solutions to give dispersions stable at room temperature. They lose ammonia upon drying and form surface coatings with the same properties as copolymers processed otherwise.

Applications. Present applications comprise inner laminate layers on aluminum foil for pouches (towelettes, condiments) and tubes (toothpaste), cable sheathing, pipe coatings, and laminates on metals and glass fiber for automotive and building applications, and on polyurethane foams for carpet underlay.

FDA regulations for direct food contact with ethylene acid copolymers exist for EAA resins containing up to 10 % acrylic acid units and EMMA resins with up to 20 % methacrylic acid units.

Prices of resins are between those of low-density polyethylenes and Surlyn A ionomers.

5.2.4. Elastomeric Acidic Copolymers

Since 1976, Du Pont has offered Vamac, a copolymer with ethylene units $-CH_2-CH_2-$ and methyl acrylate units $-CH_2-CH(COOCH_3)-$ in the molar ratio 1: 1 and a small amount of undisclosed cure site units $-R(COOH)-$. The polymer is probably synthesized by free-radical emulsion polymerization. Two carbon-black-filled masterbatches (e.g., type B-124 with 24 parts SRF carbon black and auxiliaries per 100 parts polymer) and two neutral masterbatches (e.g., type N-123 with 23 parts siliceous earth per 100 parts polymer) are available [60].

All Vamac grades can be vulcanized by diamines or hexamethylene diaminocarbamate, and N-123 also by free radicals. Vulcanized Vamacs are EE – EH elastomers according to ASTM D-2000 and SAE J-200 classifications, i.e., elastomers with continuous service temperatures up to 175 °C (E) and swelling between 20 % (H) and 80 % (E) after 70 h in ASTM oil no. 3. Vamac is resistant to hot oils, hydrocarbons, glycols, and engine cooling fluids but not to brake fluids. Its weatherability is excellent.

The heat distortion of Vamac is surpassed only by the more expensive fluoroelastomers and silicones; however, Vamac has better mechanical properties. After 30 min vulcanization at 177 °C, the rebound elasticity of B-124 is 35 %, the tensile strength 14 MPa, the ultimate elongation 440 %, and the 100 % modulus 2.9 MPa. After 7 d at 177 °C, the modulus increases to 5.3 MPa and the tensile strength to 16.5 MPa, whereas the elongation decreases to 240 %, all probably due to an after-vulcanization.

Vamac is used for tubes and seals and as a damping material. It can replace sulfochlorinated polyethylene in cables and electrical systems since it burns with little smoke of low toxicity.

5.3. Ionomers

5.3.1. Introduction

The name ionomer was originally introduced by Du Pont for (partial) salts of copolymers of olefins with small amounts of carboxyl group containing monomers, such as ethylene – methacrylic acid copolymers [61]. The term ionomer is now used as a generic term for thermoplastic and elastomeric hydrocarbon polymers with

Table 5. Industrial ionomers

Parent monomeric unit	Ionomeric unit	Ions	Trade name	Manufacturer
Thermoplastics				
Ethylene	methacrylic acid	Zn, Na	Surlyn A	Du Pont
Tetrafluoroethylene	perfluoro vinyl ether A ∗		Nafion	Du Pont
Tetrafluoroethylene	perfluoro vinyl ether B ∗		Flemion	Asahi Glass
Styrene	styrene *p*-sulfonic acid			Exxon
Elastomers and thermoplastic elastomers				
Ethylene	post-sulfochlorination		Hypalon	Du Pont
Ethylene + propylene+ nonconjugated diene	post-sulfonation		Thionic	Uniroyal
Butadiene + acrylonitrile	acrylic acid	Zn	Hycar	Goodrich

∗ Perfluoro vinyl ether: $CF_2{=}CF[O(CF_2CF(CF_3)O)_mR]$ with $R = (CF_2)_2SO_3Na$ (A) or $R = (CF_2)_nCOONa$ (B).

small amounts of partially or completely neutralized pendant acid groups which show typical ionomer properties (Table 5). Total acidic group contents (free or neutralized) are usually under ca. 10 mol %. The syntheses, structures, properties, and applications of ionomers have been described in many books [62–64], reviews [50], [65–71], handbook articles [72–74], and symposia [75–77].

The acidic monomer units of such copolymers may be directly introduced by copolymerization as in ethylene/acrylic acid copolymers, or subsequently by chemical transformation of a primary copolymer as in the sulfonation of copolymers of ethylene, propylene, and a nonconjugated diene (Table 5). In ionomers, acidic monomer units are furthermore partially or completely converted into their salts. Polymer literature restricts the term "ionic" to these salts: polymer molecules with salt groups such as $-COONa$ or $-COONH_4$ are called ionic, whereas those with groups such as $-COOH$ or $-SO_3H$ are not considered ionic but are sometimes referred to as acidic copolymers. Ionic and acidic copolymers with small proportions of ionic and/or acidic groups are always insoluble in water.

At present, only three thermoplastic ionomers (Surlyn A, Nafion, Flemion), two thermoplastic elastomers (Hypalon, Thionic), and many carboxylated rubbers (Hycar and others) are manufactured. Many other ionomers have been reported in the literature, e.g., carboxylic, phosphonic, sulfonic, and thioglycolic salts of polypentenamers [78], carboxylated and sulfonated polystyrenes [79], [80], and telechelic poly(isobutylene sulfonate) ionomers [81].

5.3.2. Structure

The first thermoplastic ionomers were copolymers of ethylene and methacrylic acids, partially neutralized with zinc or sodium compounds [82]. These Surlyn A polymers of Du Pont have much better clarity and tensile properties than comparable polyethylenes, which stimulated much research.

The enhanced properties of Surlyn A polymers were first thought to be due to decreased crystallinity and the presence of cross-linking triple ions of one bivalent metal cation (Zn^{2+}) and two carboxyl anions. It was subsequently shown that crystallinities are not markedly lower than those of the parent polymers, and that the good transparency was due to the absence of spherulites. These property changes also occur with monovalent metal cations (such as Na^+) so that other ionic cross-links must be present; these were later found to be ion multiplets and ion clusters.

Ionomers may be amorphous or partially crystalline, depending on the crystallizability of the segments of the parent monomer units. Amorphous ionomers are two-phase polymers. The continuous phase of these ionomers is amorphous and composed of parent segments with interdispersed ion pairs and ion multiplets. The discontinuous phase of amorphous ionomers consists of ion clusters of ion pairs and ion multiplets with interdispersed polymer segments. Crystallizable ionic copolymers possess crystalline regions as a third phase in addition to the amorphous phase and the ion clusters [49] (Fig. 3).

Crystalline domains do not contain acidic or ionic units; the segments in these domains are chain-folded. Acidic units are confined to amor-

Figure 3. Schematic representation of the structure of crystallizable ionomers with crystalline (lamellar) domains, amorphous regions with ion triplets (and multiplets), and ion clusters with interdispersed chain segments (e.g., zinc-neutralized low-density ethylene – methacrylic acid copolymers)

phous regions, whereas ionic units are either in amorphous regions or in ion clusters. The amorphous regions contain polymer segments with acidic or ionic units, acidic units as dimers, and ionic units as ion pairs and/or ion multiplets in a single phase. Ion clusters are separate phases that contain ion multiplets and polymer segments. The exact structure, size, and size distribution of amorphous and crystalline phases, ion clusters, ion multiplets, ion pairs, and associations of acidic groups are not known.

5.3.3. Properties

Ionic Group Content. Ionomers behave either as physically cross-linked thermoplastics or as thermoplastic elastomers, depending on the segment mobility of the parent monomer units. In amorphous polymers, the mobility is determined by the glass transition temperature, and in crystalline polymers also by the melting temperature, both relative to the service temperatures. Melting temperatures of crystalline polymers are mainly affected by the segments of the parent units and only secondarily by acidic or ionic units, which merely reduce the segment lengths of crystallizable units.

Figure 4. Glass transition temperature T_G as function of the linear charge density xq/a where x is the "metal carboxylate content" (probably in mol % of ionic units), q the cation charge (in "units of electron charges"), and a the distance between centers of charge (probably in 0.1 nm) [85]
○ $= T_G$ of ion clusters of ethyl acrylate – acrylic acid copolymers EA – AA with Li, Na, K, Cs, Ca, and Ba [84]
– $= T_G$ of amorphous domains of $[Na_2(Ca)SiO_3]_n$ glasses, salts of $[HPO_3]_n$, and salts of poly(acrylic acid) PAA

However, the glass transition temperatures T_G reflect the structure and mobility of noncrystalline phases, i.e., amorphous phases and ion clusters. Ionomers thus show two glass transition temperatures [61].

Ion pairs and ion multiplets act as cross-linking agents in amorphous phases. The higher

the concentration of these physical cross-links, the shorter are the segments between cross-links. Cooperative movements of the units in segments are affected if the segment lengths are shorter than $N_c = 30-50$ chain atoms. At $N_c < 30-50$, glass transition temperatures of amorphous phases increase linearily with the concentration of ionic units (Fig. 4).

Glass transition temperatures of ion clusters are strongly influenced by ion pair and multiplet formation. Ions of an ion pair can only move away from each other above T_G; the required work W_{el} must be proportional to kT_G. This work is given by the electrostatic interaction F_{el} and the internuclear distance a. Because $W_{el} \sim kT_G \sim \int F_{el} da$, one obtains $TG \sim q_{cat} q_{an}/a$, where $q$cat and q_{an} are the cation and anion charges. The anion charge is constant in ionomers and thus $TG \sim q_{cat}/a \sim q/a$ [83]. In copolymers, only a fraction x of the monomeric units are ionic; the glass transition temperature of ionomers must be therefore proportional xq/a [84] (Fig. 4). The glass transition temperatures of ionic clusters usually show a sigmoidal dependence on either xq/a or x.

Figure 5. Young's modulus E of ethylene/methacrylic acid copolymers with 1.7, 3.5, and 5.9 mol % methacrylic acid units as function of the degree of neutralization fN of COOH groups by NaOH (●), $Sr(OH)_2$ (▲), or $Cu(OH)_2$ (△) Reproduced with permission from [58].

Effect of Neutralization. Elastic moduli of ethylene – methacrylic acid polymers with COONa groups are higher than those of the same polymers with COOH groups (Fig. 2). Increasing neutralization of COOH groups thus leads to an increase of moduli up to degrees of neutralization of $f_N \approx 30$ mol % (Fig. 5); moduli become constant at higher degrees of neutralization, which indicates that no new cross-linking sites are formed beyond this concentration.

The situation is quite different for partially neutralized copolymers of ethylene and acrylic acid. Tensile moduli first increase with higher degrees of neutralization f_N, but do not become constant as in ethylene/methacrylic acid copolymers; instead they decrease if $f_N > 0.3$ (Fig. 6). Fracture strengths σ_B increase monotonically with higher degrees of neutralization; they do not become constant. The variation of modulus and fracture strength with degree of neutralization seems to be independent of the type of monovalent cation, whereas the elongation at break depends on the ion type, especially at high degrees of neutralization. These effects are probably due to differences in the structure and/or concentration of ion clusters; experimental data are not available.

Figure 6. Variation of tensile modulus E, fracture strength σ_B, and elongation at break ε_B with degree of neutralization f_H of ethylene–acrylic acid copolymers (experimental data from [85])

Ionic domains are present in neutralized ethylene – methacrylic acid copolymers at temperatures up to 300 °C, far above the crystallite melting temperature, according to small-angle X-ray and neutron-scattering experiments. The number of ionic domains increases with the degree of neutralization f_N. Since they represent physical cross-linking sites, they are responsible

for an increase of melt viscosity with increasing neutralization, i.e., a decrease in melt volume index (melt flow index) MVI (Fig. 7). The size of these ionic domains is not affected by the type of monovalent ion nor by the applied pressure as the similar slopes of the functions log MVI = f (f_N) show.

Figure 7. Effect of the degree of neutralization by Li^+ (○), Na^+ (⊙), and K^+ (●) on the melt volume index MVI (at 298 and 3000 MPa) (melt flow index) of copolymers of ethylene with 15 wt % acrylic acid (experimental data from [85])

Figure 8. Tensile fracture strength σ_B as a function of elongation at break ε_B of salts of sulfonated EPDM polymers (32 milli-equivalents of sulfone groups per 100 g polymer) at 25 °C (●,○) and 70 °C (△,▲) (experimental data from[86]) ●, △ = Bivalent metals; ○, ▲ = Monovalent metals

Influence of Counterion Type. The association of salt groups depends on the coordination number of the counterions and not on its valency. Monovalent ions such as Li^+, Na^+, and K^+ and bivalent ions such as Mg^{2+}, Ca^{2+}, and Zn^{2+} cause multiplet and cluster formation (Fig. 3). The effects are however quantitatively different: at 25 °C and the same elongations at break, bivalent ions lead to higher tensile fracture strengths than monovalent ions (Fig. 8). At this temperature, higher strengths are accompanied by higher elongations for the two series of bivalent and monovalent metal cations. In each series, these properties increase with increasing atomic number of the metal.

At the higher test temperature of 70 °C, ionomers with bivalent metals of group 2 of the periodic table (Mg, Ca, Ba) still follow the $\sigma_B = f(\varepsilon_B)$ relationship for 25 °C but the members of higher groups (Co, Zn, Pb) now not only lead to much lower fracture strengths but to a decrease in strength with increasing elongation at break (Fig. 8). These changes indicate that the structures of physical cross-linking sites formed by metals with higher group numbers change at higher temperatures.

5.3.4. Ethylene – Methacrylic Acid Ionomers

Many thermoplastic ionomers have been reported in the literature but only three have been commercialized: Surlyn A (Du Pont) for films, coatings, and molded articles, and two perfluorinated ionomers for membranes (Nafion from Du Pont, Flemion from Asahi Glass).

Synthesis. Surlyn A (Du Pont) is a copolymer of ethylene with ca. 10 wt % methacrylic acid; 50 % of the COOH groups are present as the sodium salt [*25608-26-8*] or zinc salt [*28516-43-0*]. CAS registers these copolymers as "2-propanoic acid, 2-methyl-, polymers," i.e., as polymers of methacrylic acid, although methacrylic acid is clearly the minority component.

The commercial synthesis of Surlyn A polymers has not been disclosed. Most likely, it is a high-pressure free-radical copolymerization of ethylene and methacrylic acid. The acid groups are then partially neutralized by rolling the polymers with metal acetates, alkoxides, carbonates, or hydroxides with release of acetic acid, alcohols, carbon dioxide, or water, respectively.

Commercial products contain either sodium or zinc. Polymers with ammonium derivatives or lithium can also be processed but these polymers are not commercial. Magnesium- and barium-containing polymers possess such high viscosities that they can no longer be processed.

Figure 9. Tensile fracture strength σ_B of copolymers of ethylene with various mole fractions x_{MAA} of methacrylic acid as function of the degree f_N of neutralization
Reproduced with permission from [58].

Structure. Surlyn A polymers have a multiphase structure consisting of crystalline regions with chain-folded polyethylene segments, amorphous regions containing ion multiplets, and ion clusters with interdispersed polyethylene segments.

The introduction of acid/salt groups into polyethylene chains prevents the formation of spherulites but does not markedly change the crystallinity. Surlyn A polymers therefore have good optical clarity (haze $< 2\,\%$), especially the low-crystallinity grades. Transparency increases with increasing degree of neutralization; it becomes constant at neutralizations $>$ca. 30 – 50 %.

Surlyn A polymers have chemical structures similar to those of alkali metal salts of long-chain fatty acids. Since the latter are nucleating agents, similar behavior can be expected from Surlyn A polymers. Upon annealing, the crystallinity of these polymers does indeed increase. Spherulites form at temperatures above ca. 90 °C, leading to haziness.

Properties. Some properties of Surlyn A resins are listed in Table 6. Crystalline regions and ion clusters all act as physical cross-linking sites for the rubbery, ion-multiplet-reinforced amorphous domains; Surlyn A polymers thus have the characteristics of high-impact multiphase polymers. Tensile strengths are higher than those of comparable polyethylenes and increase with the proportion of acid units and the degree of neutralization (Fig. 9). Stiffness and hardness are similar to those of LDPE. The various grades retain impact strengths up to their brittleness temperatures, which are between −100 and −130 °C. The continuous service temperatures of ca. 70 °C are fairly low. The elongation at break is ca. 350 %, and the abrasion resistance is excellent.

The physical cross-linking of chains by ion clusters causes high melt viscosities (low melt volume indices) which are much higher than those of comparable polyethylenes. Melt strengths are high. The cross-linking also reduces the creep under constant load.

At room temperature, Surlyn A ionomers are insoluble in all common organic solvents. They dissolve at temperatures above ca. 70 °C in 60/40 vol/vol mixtures of toluene/isobutanol, toluene/methyl isobutyl ketone, or tetrachloroethylene/butanol, or in a 70/20/10 mixture of decahydronaphthalene/diethylene glycol dimethyl ether/dimethyl sulfoxide. The polymers have good resistance to stress corrosion, except by certain combinations of detergents and alcohols. The permeability for oils and fats is low, while water vapor permeabilities correspond to those of low-density polyethylene. The polymers are readily degraded by light; UV absorbers extend outdoor service lives to ca. 2 years. Surlyn A polymers burn slowly when in contact with flames.

Carboxyl groups provide Surlyn A polymers with good adhesion to metals, glass, and paper; the adhesive properties depend on the carboxyl group content. Adhesion on impact is good, as e.g., required by the painted surfaces of molded golf balls.

Applications. The combination of good impact strength, high melt viscosity, high melt strength, good transparency, and relatively low continuous service temperatures is ideal for the manufacture of extremely thin packaging films. Such films have high tear strengths and are especially well suited for the packaging of sharp objects. Co-extruded ionomer – LDPE films are used for sterilizable packaging of foods and pharmaceuticals. Coatings of zinc-containing Surlyn A grades make glass bottles splinter-resistant. The combination of toughness and good abrasion resistance recommends the polymers for shoe soles and heels. Other applications

Table 6. Properties of Surlyn A Resins

Property	Na Resin	Zn Resin
Density, g/cm^3	0.94	0.94
Melting temperature, °C	94	95
Heat deflection temperature (455 kPa), °C	40	41
Thermal expansion coefficient, K^{-1}	14 × 10-5	16 × 10-5
Melt flow index, g/10 min	1.3	5.5
Flexural modulus, MPa	220	130
Tensile strength at yield, MPa	12.4	8.3
Tensile strength at break, MPa	29	21.4
Elongation at break, %	450	500
Tensile impact strength, kJ/m^2	1160	925
Notched impact strength, J/m	610	no break
Hardness (Shore D)	60	54

are sheathing of electric cables and wires, automotive parts, and floor mats. Molded articles can be directly painted.

Closed-cell Surlyn A foams with densities of 50 – 700 kg/m^3 can be produced by extrusion or injection molding. Applications include carpet backings, ski boots, hockey sticks, helmets, and tennis court foundations.

5.3.5. Fluorinated Ionomers

Precursors of fluorinated ionomers are manufactured by free-radical copolymerization of tetrafluoroethylene (TFE) with perfluorovinylethers (FVE)

in molar ratios of 5 – 10 mol TFE per mole PVE [87], [88]. VFE-A is synthesized by reaction of hexafluoropropylene oxide (from the oxidation of TFE) with the sultone from the addition of sulfur trioxide to tetrafluoroethylene. Copolymers of TFE and VFE-A are known as XR Resins (Du Pont) whereas copolymers of TFE and VFE-B are called Flemion (Asahi Glass).

XR Resins can be melted and fabricated into membranes and tubes by conventional processing methods for thermoplastics. The $-SO_3F$ end groups are then saponified by hot caustic soda to give $-SO_3Na$ end groups, which in turn are converted into sulfonic acid groups with, for instance, nitric acid.

Du Pont manufactures articles with free sulfonic acid groups as films, tubes, or laminates under the trade name Nafion. Similar carboxylated fluoro ionomers are produced by Asahi Glass under the trade name Flemion. These polymers are permselective [89]: they allow the passage of cations but not of anions and are therefore used as membranes for electro-chemical processes, e.g., for the production of sodium hypochlorite. The exchange capacity of such resins is ca. 0.85 mmol/g, the fracture strength of resins with ca. 25 % water content ca. 21 MPa, and the elongation at break ca. 150 %. The strength can be increased by reinforcement with fabrics made from polytetrafluoroethylene fibers [90].

5.3.6. Sulfochlorinated Polyethylene

Simultaneous chlorination by Cl_2 and sulfonation by SO_2 of polyethylenes in homogeneous solution under the action of free-radical initiators or light leads to polymers with $-CH_2-$, $-CHCl-$, and $-CHSO_2Cl-$ groups in the approximate ratio 100 : 30 : 1. The polyethylene segments of these polymers are too short to crystallize, and the polymers thus behave as elastomers because of the low glass transition temperature (actual data unknown). Du Pont manufactures chlorosulfonated polyethylenes (CSM) in various grades (different CAS numbers) under the name Hypalon. Apart from a handbook article [91], little has been published about CSM polymers.

CSM polymers can be cured by way of the SO_2Cl groups [92]. The white polymers need no reinforcing fillers and can be used for many colored products. The presence of polar Cl and SO_2Cl groups provides the elastomers with excellent resistance to oil and ozone compared to standard synthetic rubbers. The maximum service temperature is ca. 120 °C.

5.3.7. Sulfonated EPDM Polymers

Synthesis and Structure. EPDM polymers are produced by Ziegler – Natta copolymerization of ethylene (E), propylene (P), and a small amount of a nonconjugated diene, preferably 5-ethylidene-2-norbornene (EN). The amorphous, rubbery polymers contain the monomeric units E, P and EN; the latter can be sulfonated by $H_2SO_4/(CH_3CO)_2O$ to sulfo units SEN [73]:

Sulfo-EPDMs can be neutralized with metal alkoxides or other bases, either in solution with subsequent precipitation of the neutralized polymer or by reactive milling of the polymer in an extruder. These thermoplastic elastomers were developed by Exxon and are now being commercialized by Uniroyal under the trade name Thionic.

Figure 10. Tensile fracture strength σ_B as function of elongation at break ε_B of sulfonated EPDM ionomers before (○–○, bivalent ions only) and after (●– – –●) plasticization with zinc stearate (experimental data from [86])

Properties. Mechanical properties of sulfo-EPDM ionomers depend strongly on the type and concentration of cations (Fig. 8). Tensile strengths of these ionic polymers are typically much more enhanced over those of the acidic base polymers as compared to other ionomers.

The strong associations caused by ion clusters decrease with increasing temperature (Fig. 8). Even then the melt viscosity is very high at the usual processing temperatures. The Mg, Ca, Co, Li, Ba, and Na ionomers of Figure 8 typically have apparent melt viscosities between 55×10^4 Pa · s (Mg) and 51×10^4 Pa · s (Na) at 200 °C and a shear rate of 0.88 s^{-1}; for unknown reasons, melt viscosities of Pb and Zn ionomers are much lower (33×10^4 and 12×10^4 Pa · s, respectively [86]. Lead and zinc ionomers also exhibit melt fracture at higher shear rates (88 and 147 s^{-1}) than the other ionomers ($< 0.88\ s^{-1}$).

The high melt viscosities can be lowered by ionic-domain "plasticizers" such as zinc stearate [86]. Such additives interact preferentially with the ionic clusters, lessen the bonding in the cluster region and thus decrease the melt viscosity. Despite its designation as local or specific "plastification", the phenomenon is not a plastification in the scientific meaning of the word since glass transition temperatures are not affected. "Plasticized" zinc and lead sulfo-EPDMs show also higher fracture strengths than the corresponding unplasticized ionomers (Fig. 10). The phenomenon seems to be due to a reduction of the strength of the cross-linking ion clusters upon shearing the melt

1. Introduction

Spirits are distilled alcoholic beverages made from ferments of plant carbohydrates, with the exception of fermented whey. Their origins are lost in history, but it is reputed that alchemists in the ancient civilizations of China, Egypt, and Greece had knowledge of distillation and may have produced distilled spirits from existing alcoholic ferments such as ales and wines. The knowledge of distillation spread to Western Europe in 1000 – 1100 A.D. from Arabian practitioners, possibly by soldiers returning from the Crusades or via the Moors in Spain. However, spirit production remained mainly in the hands of monks and alchemists until 1400 – 1500. Thereafter, there was a gradual introduction into the general population. In the rural economies of those times, small-scale distillation became widespread, and most landowners and many smaller farmers possessed distillation equipment. The relatively crude spirit was commonly termed aqua vitae, the water of life. Local translation and modification of this name led to the modern terms whisky and vodka. Industrialization brought the commercialization of distilled beverages, while European colonization and increased trading links resulted in the establishment of spirit production in most parts of the world, except where there were legal prohibitions or inadequate supplies of raw materials [1–3].

Early distillation equipment consisted of a vessel in which the alcoholic ferment was heated. The evaporated alcoholic vapor passed to a long tube connected to the head of the heating vessel. Condensation of the spirit occurred as the vapors passed through the cool tube. Originally the condensation tube was air cooled, but this was improved by immersing a coiled tube, known as a worm or a serpentine, in water. This type of still is known as a pot still or an alembic. The essential features are embodied in the traditional Charentaise still (Fig. 1).

Pot stills were normally operated in a batch fashion, but in the early 1800s a number of methods of continuous distillation were introduced. The most successful proved to be the Coffey still, invented by the Irishman, AENEAS COFFEY. His still, outlined diagrammatically in Figure 2, consisted of two columns, the rectifier and the analyzer, which is also known as a beer still. The latter is essentially a stripping column, in which alcohol and other volatiles are continuously evaporated from a feedstock of fermented material, introduced at the top of the column, by a flow of steam from the bottom. The vapors pass to the rectifier, in which the analyzer feedstock is preheated by traveling through a coiled tube. A series of distillations – i.e., condensation on the coiled tube and revaporization – occurs up the length of the second column. The least volatile compounds are most easily condensed while the most volatile are rapidly revaporized, resulting in a gradient up the column equating to increased volatility. The spirit product, consisting mainly of ethanol, is drawn off the column near the top. This series of "purifying" distillations is known as rectification, from which the name of the column derives. The principles of the Coffey still have been further refined through the use of sieve and bubble-cap plates [3–5].

Continuous distillation produced lighter-flavored spirits and was more economical than

pot distillation. The latter is now used principally in the production of heavily flavored spirits such as Scotch malt whisky, Cognac, and certain rums. In a number of cases, attempts have been made to protect the traditional character of certain spirits by restricting the maximum alcohol concentration of the distillate, thus prohibiting excessive rectification (e.g., Bourbon whiskey). Such products are usually made by single- column continuous or pot distillation [2], [3], [5].

Figure 3. Flow sheet of major steps in distilled alcoholic beverage production

Besides the engineering developments, the range of raw materials used was extended as knowledge of spirit production spread. Any source of carbohydrate which could be economically grown was utilized. Regional spirit

types developed to reflect the abundance of local crops, and gradually the modern categories of products were established. All processes have the basic steps outlined in Figure 3. Variations at each stage have led to the differences between and within categories, resulting in the wide array of spirit drinks available worldwide. Most are consumed in their area of production, but a few are distributed internationally, such as Cognacs and Scotch Whisky [4], [6].

2. Types of Spirit Drinks

There are two distinct divisions in the distilled alcoholic beverages. In the first, the product is characterized by flavors emanating from the raw materials and subsequent fermentation, even though some rectification may occur during distillation. The spirit is often further modified by aging, termed maturation, in wooden casks. This division includes categories such as whiskies, rums, wine spirits, brandies, and tequila. The second group contains products which gain their main characteristics from downstream processing, such as flavor addition. Although the spirit base may be one from the first grouping, highly-rectified neutral spirits are frequently used. The individual products are categorized by the exact nature of the additional processing. This division includes gin, aquavit, liqueurs, and anis.

Throughout the world, there are numerous types of local spirits, which have similarities to the major categories described below. There is also some variation in local definitions and terminology; therefore the following sections mainly follow the conventions of the EC Spirit Drink Regulations [7].

These regulations define a spirit drink as:

1) An alcoholic liquid intended for human consumption
2) Having particular organoleptic properties and a minimum alcoholic strength of 15 vol %, except for egg liqueurs/advocaat/avocat/Advokat which are allowed a minimum of 14 vol %
3) Produced
   a) either directly by the distillation, with or without added flavorings, of natural fermented products and/or by the maceration of vegetable substances and/or the addition of flavorings, sugars or other sweetening products (listed in the regulations) and/or other agricultural products to ethyl alcohol of agricultural origin and/or to distillate of agricultural origin and/or to spirit (as defined in the regulations)
   b) or by the mixture of a spirit drink with one or more other spirit drinks; ethyl alcohol of agricultural origin, distillate of agricultural origin or spirit; one or more alcoholic drinks; or one or more drinks

Whiskies. Whisky, or whiskey, as it is spelled in Ireland and the United States, is a distilled alcoholic beverage, made from a mash of cereals fermented by yeast, and which has been matured in wooden casks. The best known whiskies are those made in Scotland, Ireland, the United States, Canada, and Japan, although local whiskies are made in many cereal-growing regions. The EC definition stipulates a maturation period of at least three years in wooden casks not exceeding 700 L in capacity. Distillation must be carried out at less than 94.8 vol %, whereas in the United States the maximum is 95 vol %.

The UK definition for Scotch Whisky restricts the wooden casks to oak and prohibits the use of added enzymes, which are permitted elsewhere. Malted barley, to which only the whole grains of other cereals may be added, must be included in the mash [8]. Scotch malt whisky is made from a mash of malted barley and is pot-distilled, whereas the mash for Scotch grain whisky includes ca. 85 % of unmalted cereal, usually wheat or maize, and is column distilled. The individual processes are described in greater detail in Chapter 3. Although numerous malt whiskies and a few grain whiskies are marketed, over 95 % of all Scotch whisky sales are of blended whisky, that is, a mixture of malt and grain whiskies.

Japanese and Irish whiskies are made in a similar way to Scotch, although the Irish make some pot-distilled product from a mash that includes a proportion of unmalted cereals. There are no restrictions on the use of added enzymes. North American whiskies are made from mashes in which unmalted cereals predominate and they are column-distilled. In the United States, bourbon and rye whiskies are made from fermented mashes of not less than 51 % maize and 51 %

rye, respectively. These whiskies must be distilled at an alcoholic strength ≤ 80 vol %, thus restricting the degree of rectification, and stored at not more than 62.5 vol % alcohol in charred new oak casks. If they are aged for at least two years, they may be termed straight whiskey, as are other whiskies made under the same restrictions from wheat, malted barley, and malted rye. American blended whiskey contains ≥ 20 vol % of straight whiskey (calculated at 50 vol % alcohol) blended with other whiskey and/or grain neutral spirits. The latter are distilled at or above 95 vol % alcohol [2], [3], [9].

Grain spirit is an EC designation for a type of spirit drink produced by the distillation of a fermented mash of cereals and having organoleptic characteristics derived from the raw materials used. In Germany and other German-speaking, traditional producing regions, the term "Korn" or "Kornbrand" may be used if the grain spirit is obtained without any additive. The designation "grain brandy" may be applied, if the grain spirit is distilled at < 95 vol % alcohol [7]. The flavor of individual products is influenced by the actual cereals in the mash and they have some resemblance to unaged whisky spirits.

Rum is a spirit produced by distilling fermented sugar cane juice, syrup, or molasses. Some countries, such as Finland, allow the use of fermented beet molasses, but this is not generally recognized. Rum-like products may go under other names, such as "cane" in South Africa and "cachaca" in Brazil. Production is mainly centered in the Caribbean and other sugar cane growing areas. In some developing countries, local molasses spirits are sold as "whiskies" and "brandies" rather than their true designation as rum.

Light-bodied rums are distilled on multicolumn continuous distillation systems, whereas heavy-bodied rums are produced by using pot stills, particularly in Jamaica and Guyana. Jamaican law prohibits the manufacture of rum other than as part of a sugar refinery complex. The maximum distillation strength in EC regulations is 96 vol % alcohol, whereas the United States has a maximum of 95 vol %. There is no general requirement for maturation, although many rums do undergo aging, in which case the cask size should not exceed 700 L nominal capacity. Products marketed as "dark rums" have normally been aged, but some of their color may arise from the addition of caramel [2], [3], [10].

Wine Spirit. The EC designation "wine spirit" refers to a spirit drink produced by the distillation of wine or redistillation of a wine distillate at a strength of < 86 vol % alcohol. The distillate should contain a quantity of volatile substances, other than ethanol and methanol, ≥ 125 g per hectoliter of absolute alcohol. If the product is aged, it can continue to be termed "wine spirit" but must meet the aging regulations stipulated for brandies.

This category includes unaged products of the eau-de-vie de vin type. However, also included are matured spirits which have, until now, been more usually called brandies, such as cognacs and armagnacs. The latter are produced by single column distillation, although a few distillers use pot stills, similar to the Charentaise alembic (Fig. 1) [6], [7].

Brandy is a term used widely to describe distillates made from the fermentation of fruits or their musts. It is normally prefixed by the fruit name but, in the case of grapes, is used alone. In the United States, all fruit brandies must be distilled at < 95 vol % alcohol and those from grapes at < 85 vol %. If the latter limit is exceeded, the spirit is termed neutral brandy. US law stipulates a minimum aging period of two years in oak casks [2].

The EC designation for "brandy" and its German equivalent "Weinbrand" is restricted to grape distillates and is complimentary to the wine spirit designation. The spirit drink is produced from wine spirit, whether or not it is blended with wine distillate distilled at < 94.8 vol % alcohol, provided that the latter does not exceed 50 % of the final product. Aging should take place for a minimum of six months in oak casks with a capacity of < 1000 L or for a minimum of one year in larger oak receptacles. Cognacs and armagnacs also meet this definition. The distinction is that brandies, containing the lighter, double- or multiple- column distillates, cannot be defined as wine spirits [7].

Fruit Spirits. The products which are known in many countries as fruit brandies,

excluding those from grapes, are included in this EC designation. Distillation must be at < 86 vol % alcohol, similar to wine spirits, but the volatile substances must equal or exceed 200 g per hectoliter of absolute alcohol. Fruit spirits may also be produced by macerating partly fermented or unfermented fruits in neutral spirit or some other distillate at not less than 100 kilograms of fruit per 20 L of absolute alcohol, followed by distillation. This category includes well-known drinks, such as Kirschwasser, and numerous regional "eau-de-vies" [7], [11].

Cider Spirit, Cider Brandy, and Perry Spirit. This category includes spirit drinks which meet the requirements for fruit spirits and are made exclusively by the distillation of cider or perry, ferments of apple and pear, respectively. The best-known product is probably calvados.

Grape Marc Spirit. The debris left in the grape press can be fermented and then distilled to produce a product known as grape marc or grape marc spirit. The designation "grappa" may be used for such products made in Italy. The EC limits distillation to < 86 vol % alcohol and stipulates that the volatile substances, other than ethanol and methanol, should be equal to or exceed 140 g per hectoliter of absolute alcohol.

Fruit Marc Spirits. Fruit marc spirits are made in a similar way to grape marc spirit by the fermentation and subsequent distillation of fruit debris or marc. The maximum distillation strength is the same, but the minimum volatile substances content is 200 g per hectoliter of absolute alcohol.

Tequila is made in the Mexican region of that name from a fermented substrate derived from the heads of the agave cactus, *Agave tequilana* Weber. The cactus is rich in the polysaccharide inulin which is broken down on heating to yield fructose monomers. The substrate may be supplemented with sugar up to 30 % of the total. Distillation is by two-stage pot distillation, but the final product may contain up to 50 % neutral spirits. There is no legal maturation requirement, but many tequilas are aged in oak casks [2], [3].

Vodka. The original vodka of Russia and Eastern Europe was essentially the local version of "aqua vitae" made from any readily-fermentable material and distilled in pot stills. With time, the process developed to include charcoal filtration to remove "impurities", and in the 1800s continuous column distillation was introduced. Although more refined, many vodkas from this region retain some flavors from the raw materials and the fermentation, and many contain added flavors [6].

The vodka of Western Europe and North America is made from neutral spirits, i.e., highly-rectified spirit produced by multicolumn continuous distillation. In the United States, the minimum distillation limit is 95 vol % alcohol and the spirit must be further treated with charcoal or activated carbon or redistilled so that it has no character, aroma or taste other than ethanol, before it can be termed vodka. If pronounced flavorings are added, they must be included in the product description. The EC regulations are similar. Nonpronounced flavorings may be used to give a more mellow taste. The neutral spirits must, however, be distilled at a higher strength and meet the EC specification.

The EC specification for neutral spirit (ethyl alcohol of agricultural origin) [7] is as follows:

1)	Organoleptic characteristics	no detectable taste other than that of raw material
2)	Minimum alcoholic strength	96.0 vol %
3)	Maximum level of residues (in grams per hectoliter of 100 vol % alcohol)	
	Total acidity, as acetic acid	1.5
	Esters, as ethyl acetate	1.3
	Aldehydes, as acetaldehyde	0.5
	Higher alcohols, as 2-methyl-1-propanol	0.5
	Methanol	50
	Dry extract	1.5
	Volatile bases containing nitrogen, as nitrogen	0.1
	Furfural	not detectable

The methanol limit may, in future, be reduced to 20 grams per hectoliter of 100 vol % alcohol.

The raw material can be any source of fermentable substrate, provided it is of agricultural origin (e.g., cereals, potatoes, cane and beet molasses, fruits, and whey, a byproduct of the dairy industry). Some countries, such as Finland, restrict the raw materials to those traditionally used in the original vodka-producing region, namely cereals and potatoes [2], [7], [12].

Fruit Spirit Drinks. Although similar in name to fruit spirits, this EC designation applies to beverages made by macerating fruit in neutral alcohol or other spirits without further distillation. Other flavors may be added but the characteristic taste and color of the drink must come from the fruit used. The minimum proportion of fruit is 5 kg per 20 L of absolute alcohol [7], [11].

Juniper-Flavored Spirit Drinks. A number of distilled beverages are produced by flavoring neutral spirit and/or grain spirit and/or grain distillate with juniper (*Juniperus communis*) berries. The most internationally famous are gin and genever, although there are many localized products, such as German "Steinhäger" (Steinhagen, Gütersloh). Other approved flavorings may be used, but the organoleptic characteristics of juniper should be discernable, except in the case of genever. In contrast, gin is required to have a predominant juniper taste. The term "distilled gin" is restricted to products obtained by redistilling neutral spirit over or with juniper berries and other botanicals and flavorings. Gin stills are modified pot stills. In some, the botanicals are held in perforated trays in the head of the still through which the alcoholic vapors pass, whereas in others the botanicals are loaded into the body of the still with the neutral spirit. "London gin" is a type of distilled gin rather than a geographical designation. There is no general requirement for aging, but some gins are matured in wooden casks, particularly some traditional genever brands and some premium gins [6], [7], [12].

Caraway-Flavored Spirit Drinks. Caraway (*Carum carvi*) is widely used to flavor spirit drinks, particularly in Northern Europe, such that the EC has a separate category for such beverages. Internationally, Danish "akvavit" is the best-known. However, in Scandinavia other drinks carry this name, or its synonym "aquavit", but are not flavored with caraway, and the term should be regarded as covering a range of flavored and unflavored distillates akin to Russian vodkas.

The EC designation stipulates that for a caraway-flavored spirit drink to carry the akvavit or aquavit name, they must be flavored by a distillate of plants or spices; that is, essential oils are prohibited. The characteristic flavor must be attributed to distillates of caraway and/or dill (*Anethum graveolens* L.) seeds [6], [7].

Aniseed-Flavored Spirit Drinks. Aniseed-flavored spirits are produced by flavoring distillates, particularly neutral spirit, with natural extracts of star anise (*Illicium verum*), anis (*Pimpinella anisum*), fennel (*Foeniculum vulgare*), or any other plant which imparts primarily the characteristic aniseed aroma and taste. The beverage may be produced by (1) maceration or distillation, (2) redistillation of the alcohol in the presence of the aniseed-flavored seeds or plants, (3) addition of distilled extracts of the plants, or (4) a combination of these methods. Although other seeds and natural plant extracts may be used, the drinks should have a predominant aniseed taste.

The characteristic flavor of products called "anis" must be derived exclusively from anise, and/or star anise, and/or fennel. The term "distilled anis" may be used if at least 20 % of the product's alcohol has been distilled in the presence of the seeds.

Aniseed-flavored drinks called "pastis" must also contain natural extracts of liquorice root (*Glycyrrhiza glabra*). They, therefore, contain colorants known as chalcones as well as glycyrrhizic acid, which has an EC limit of 0.05 – 0.5 g/L. The EC also limits sugar to < 100 g/L and anethole to 1.5 – 2 g/L.

"Ouzo" is an aniseed-flavored spirit drink produced exclusively in Greece by blending alcohols flavored by distillation or maceration of aniseed and possibly fennel seed, mastic from a lentiscus indigenous to the island of Chios (*Pistacia lentiscus Chia* or *latifolia*), and other seeds, plants, and fruits. The alcohol flavored by distillation must represent at least 20 % of the product's alcohol and the distillation must be carried out in traditional discontinuous copper stills of ≤ 1000 L capacity at 55 – 80 vol % alcohol. The product must be colorless and have a sugar content of ≤ 50 g/L [6], [7].

Arrack and **raki** are terms used throughout the Middle East, the Balkans, and southeast Asia to describe a wide range of local distilled beverages made from various raw materials, such as grapes, dates, palm sap, figs, molasses, rice, and other cereals. It is often flavored with aniseed and has some resemblance to anis.

Unflavored products could be classified in other categories; for example, molasses-based arracks are akin to rums [6].

Bitters. Bitter-tasting spirit drinks are produced by flavoring neutral spirit with approved flavoring such that the product has a predominant bitter taste. They are most widely known as pick-me-ups or hangover cures, but they are also consumed as aperitifs diluted with ice and soda, or neat as digestifs. They may also be included in cocktails; for example Angostura bitters is an essential ingredient of pink gin. The alternative name "amer" is also used [6], [7].

Liqueurs and Cordials. Cordial is the American term for products called liqueurs elsewhere. They are made by flavoring and sweetening neutral spirit or a spirit drink or a combination thereof and may also contain added agricultural products, such as cream, milk, egg, fruit, wine, or flavored wine. In the United States, the minimum sugar content is 2.5 wt % and the product may be designated "dry" if the level is less than 10 wt %. The EC regulations stipulate a minimum of 100 g/L expressed as invert sugar and restrict the use of the term "crème de" followed by the name of a fruit or the raw material used, excluding milk products, to liqueurs containing at least 250 g/L of sugar. The blackcurrant liqueurs named "crème de cassis" must contain at least 400 g/L of sugar. Gentian liqueurs, prepared with gentian as the sole aromatic substance, and cherry liqueurs, made solely with alcohol which is cherry spirit, are allowed reduced minimum sugar contents of 80 g/L and 70 g/L, respectively.

Egg liqueur, commonly known as advocaat or similar names, is regulated in the EC to contain egg yolk, egg white, and sugar or honey. The egg yolk content must exceed 140 g/L and the sugar or honey must be at least 150 g/L. Similar products of lower egg yolk content, to a minimum of 70 g/L, are termed liqueur with egg [2], [6], [7].

3. Typical Production Processes

There is such a vast range of process variations in the distilled alcoholic beverage industry that it is not possible to effectively cover them here. Instead, a few examples are described to illustrate the principles used in some of the major categories.

3.1. Cereal-Based Processes

Cereals are the major raw materials used to produce international categories of spirit drinks, such as whiskies, many more localized categories, such as Korn, and a large fraction of the neutral spirits or cruder distillates which are further processed, by flavoring or otherwise, into numerous categories of drinks (e.g., vodka, gin, etc.). There are two distinct classes of distillery processes typified by those used in the Scotch whisky industry.

3.1.1. Malt Whisky Production

Sugars are present in cereal seeds in the form of the storage polysaccharide, starch. The latter is not readily fermented and must be broken down into more easily utilizable subunits. The traditional method to achieve this was by the process known as malting, which was most successfully achieved with barley. Malting involves three steps: steeping, germination, and kilning. During steeping, water is added, usually in stages with air rests between, until the moisture content is ca. 45 %. This rehydrates the grain, particularly the endosperm area in which the starch is stored in granules, and stimulates the embryo plant to commence germination. The embryo secretes gibberellic acid, a plant hormone, which induces a layer of cells, known as the aleurone layer, to excrete a range of hydrolytic enzymes into the endosperm. Some enzymes are also secreted by the embryo portion of the grain.

The initial enzyme actions are of a cytolytic function, in which glucanase enzymes digest the glucan cell walls of the endosperm and protease enzymes hydrolyze the protein matrix contained therein, releasing the enclosed starch granules. Carbohydrase enzymes, of which α-amylase, β-amylase, and limit dextrinase are the most important, start to hydrolyze the starch. Nutrients released by the enzymes are used for embryo growth. The maltster must balance the breakdown of the endosperm, known as modification,

against the loss of potentially fermentable carbohydrate.

Figure 4. Flow sheet of Scotch malt whisky process

When modification is judged to be sufficient, germination is arrested by drying or kilning the barley gently in a stream of warm air. Traditionally, the heat for kilning in many parts of Scotland was obtained from peat fires. On burning, peat releases a phenolic smoke which impregnates the grains as they dry. Many of these volatiles pass through subsequent processing stages to impart a phenolic or peaty taste to the whisky. To maintain this characteristic, many malted barleys are still peated, although the peat smoke may be introduced into the drying air stream from an ancillary furnace rather than being the main source of heat. The malted barley is dried to 3.5 – 5 % moisture. The enzymes are inactive at this level, although some of the most heat-labile are largely destroyed by the heat of kilning. Besides killing the embryo and suspending enzyme activity, the malted barley is also prepared for easy storage and subsequent milling [13–17].

The major steps of the malt whisky process after malting are outlined in Figure 4. Prior to milling, dust, stones, metal, and other extraneous materials are removed. The mills are most frequently of the 4-roller type, but modern plants have 5- and 6-roller mills. The malted barley is ground to produce a grist, which contains about 10 % fine flour and 20 % coarse husk fractions, with the rest as medium-sized fragments. Care must be taken that the milling is neither too fine nor too coarse, as both can result in poor mashing performance, by affecting, respectively, malt wort run-off or starch extraction and hydrolysis.

The grist is made into a mash by mixing with hot water, to give an initial temperature of ca. 65 °C, in a mixing apparatus as it is discharged into the mash tun. Sometimes known as a lauter, this vessel has a false bottom, with apertures about 0.5 mm wide, through which the solid-free malt wort is separated from the rest of the mash. After discharge into the tun, the mash is mixed. By this time, the starch has been liquified (gelatinized) and thereafter is rapidly hydrolyzed by the amylase enzymes. At the temperature of the mash, limit dextrinase and, to a lesser extent, β-amylase are inactivated within a short period of time, as are many of the other barley enzymes, such as the proteases and glucanases. However, to maximize conversion, the mash is normally allowed to sit for 20 – 60 min. During this time, the husk settles on the false bottom to form a filtration medium through which the malt wort is drawn, thus clarifying it. The worts are drained by gravity into a balancing tank, from whence they are pumped via a heat exchanger to the fermentation vessels, termed washbacks. Further quantities of water, named sparges, of higher temperature are added to the mash batchwise or by continuous spraying. Only the strongest of these extracts is pumped to the fermenters, while the rest are collected for recycle in the next mash [16], [18].

Although the use of added microbial enzymes is prohibited in the Scotch whisky process, this is not the case in other countries. Added amylases and/or glucanases can aid conversion and wort run-off, especially if poorer quality, less well modified malted barley is used. Similar additions, usually of glucoamylase, to the fermentation stage can help maximize yields. In Ireland, similar styles of mashing are sometimes

carried out with malted barley and unmalted cereals, most usually barley or oats.

The traditional fermentation vessels are wooden vats with removable, segmented lids and slightly-angled bottoms to ease discharge, but modern distilleries have totally-enclosed, cylindrical, stainless-steel vessels with conical bottoms. They are not attemperated in Scotland, but in warmer climates this can be a necessity. In the uncontrolled system, the initial temperature is ca. 21 – 22 °C which rises to about 33 °C due to the heat generated during fermentation [19–21].

The yeast is added during washback filling, once the temperature has stabilized. Specialized distilling strains of *Saccharomyces cerevisiae* are used, singly or in combination, frequently supplemented with waste brewery yeasts [22], [23]. The sugar content of the initial wort is 120 – 150 g/L, with the main components being maltose ca. 55 %, maltotriose ca. 15 %, glucose ca. 8 %, fructose ca. 7 %, sucrose ca. 2 %, and the rest as oligosaccharides and minor sugars. The main nitrogen source is amino acids from barley protein hydrolysis. The initial free amino nitrogen concentration is ca. 0.3 g/L. The fermentation is relatively rapid due to a combination of the characteristics of the yeast strains, a relatively high inoculation level (10 – 20 million yeast cells/mL of wort), the wort composition, and the moderately high temperature. The main yeast fermentation is normally complete in ca. 40 – 48 h [20], [21].

The fermented wort is called wash, although the term beer is used in some countries. It has an alcoholic strength of ca. 7 – 7.5 vol %. It undergoes pot distillation, in copper stills, of a similar general design to that illustrated in Figure 5, although some distilleries use traditional worm condensers. The wash is first distilled to produce a distillate of ca. 18 – 20 vol % alcohol, known as low wines. A second distillation takes place from which three fractions are collected; the first runnings (foreshots or heads), the main spirit product, and the last runnings (tails or feints). The heads and tails are collected and mixed with the low wines to charge the next distillation. The middle fraction is filled into oak casks for maturation into whisky. In Ireland and a few Scottish distilleries, triple rather than double-distillation is practised, with similar recycling of heads and tails fractions [5], [24].

A major aim of the malt whisky process is to produce desirable flavors as well as ethanol. The new distillate contains alcohols, esters, carbonyl compounds, acids, sulfur compounds, phenolics when peated malt is used, and traces of nitrogen compounds. A few, such as the peaty flavors, may emanate from the raw materials, but the majority, or their precursors, are formed during fermentation by the action of yeast and other microbes which may be present [25], [26]. It is now known that many of the reactions, such as esterification, continue during distillation, often catalyzed by the copper of the still construction [27]. They also continue during maturation, but at a slower rate. However, many other changes occur as the spirit ages. Lignin and hemicellulose breakdown products, such as vanillin and sugars, are extracted by ethanol. Oxygen permeating through the cask pores participates in oxidation reactions, but there is also a loss of ethanol by evaporation amounting to ca. 2 % of the contents per year in cool climates, such as in Scotland, and higher in warmer environments. Besides the chemical reactions, various physical changes take place, such as alterations in solubilities and the formation of chemical complexes. All of the reactions, extractions, and interactions combine to convert the relatively harsh, new spirit into the more mellow and smooth, matured product [28].

3.1.2. Grain Whisky Production

The basic steps of the Scotch grain whisky process, as illustrated in Figure 6, differ in a number of ways from malt whisky production. The majority of the cereal mash is composed of unmalted cereals, usually maize or wheat, but in similar processes elsewhere, barley or rye. These are cooked in batch or continuous cookers at atmospheric or elevated pressures and at temperatures of 100 °C or higher to gelatinize the starch. Traditionally the unmalted grains were milled, but this is not necessary if pressure cooking is followed by sudden release to atmospheric pressure, which results in the grains' "exploding". The gelatinized mash is cooled to 63 – 65 °C and mixed with malted barley grist of high amylolytic enzyme content. Some distillers use green malt (i.e., unkilned malted barley), which

Figure 5. Schematic of Scotch malt whisky pot still

retains a higher proportion of enzymes, due to the lack of heat destruction in the kiln.

Although a few distillers continue to lauter the mash to extract a solid free wort, the majority now discharge the whole mash into the fermenters [9], [18], [29]. The fermentation sugars are of a similar composition to malt wort, although more concentrated, but the fermentation rate tends to be slower due to lower concentrations of assimilable nitrogen. The fermented wash (10 – 12 vol % alcohol) is continuously distilled in two- column stills, similar to the Coffey still (Fig. 2), or in more refined multicolumn systems. Many of the secondary, volatile compounds are rectified out, so that the new spirit is much lighter than its malt whisky counterpart. With both types, the maturation casks are normally of Spanish or American oak [9].

In other countries, microbial enzymes are used instead of malted barley to achieve the conversion of starch to fermentable sugars, although 2 – 3 % malt may be retained for flavor purposes, compared with the usual level of 12 – 15 % used in Scotland. Heat-stable bacterial α-amylases may be added as the mash is heated in the cooker, to aid liquification. Fungal α-amylases and glucoamylases are added on cooling to achieve conversion. In some cases, the latter is added just prior to, or at the time of discharge into the fermenters, in which most of the starch conversion occurs [2], [3]. Many of the commercial enzymes contain carbohydrases other than glucoamylase or α-amylase and may also have protease activity [29]. The process is essentially the same in the production of grain neutral spirits, except that the spirit is highly rectified in multicolumn stills. Other starch sources, such as potatoes, can be processed in a similar manner [12].

More highly-flavored grain spirits, such as bourbon and other American straight whiskies, are produced by using single- column stills, termed beer stills, often followed by redistillation in a continuously fed pot still, called a doubler (Fig. 7). Wash, or beer as it is termed in the United States, is fed into the still at the top of the stripping section, usually consisting of about 14 plates. The vapors pass through an entrainment plate that prevents the rise of solids, into a rectifying section of 3 or 4 plates. The doubler

residues are recycled into the beer still [2], [3], [30].

Figure 6. Flow sheet of Scotch grain whisky process
Steps within broken lines are not universal.

3.2. Pot-Distilled Rum

Continuous distillation is the prevalent process in rum manufacture. However, traditional, pot distillation is used especially in the English and French speaking West Indies, to produce highly-flavored distillates, which may be sold as such, but are most commonly used in blending. The main flavor components are esters and the rums are traded according to their ester contents. Some of the most strongly flavored rums are produced in Jamaica, where the addition of limings, a scum from molasses, and dunder, the residue after molasses wash distillation, are added to the fermentation. These materials support a population of bacteria and wild yeasts which produce higher concentrations of esters or their precursors during storage and subsequent fermentation compared with standard distilling yeasts.

The traditional pot distillation system (Fig. 8) consists of a series of vessels. The vapors from the main pot pass through the others, often termed retorts, in which condensation and redistillation occur. Tails and heads from the final condensation are recycled to the first and second retorts, respectively. This system concentrates the esters. In Guyana, some of the pot still bodies are made of wood, although the heads and condensers are of copper, which catalyzes reactions such as esterification [6], [10], [31].

3.3. Cognac

Traditional spirits with geographic designations often have national rules governing the production processes. True cognac can only be produced in the Charente and Charente-Maritime departments as well as two small zones in the Deux Sèvres and Dordognes departments of France. For sub-appellation purposes and distillate classification, there are six distinct production areas: Grande Champagne, Petite Champagne, Borderies, Fins Bois, Bons Bois, and Bois Ordinaires. The grapes are white varieties, of which at least 90 % should be Ugni Blanc, Folle Blanche, and Columbard, while the rest can be from Blanc Ramé, Jurançon Blanc, Montils, Sémillon, and Sélect. The continuous Archimedes press is prohibited and no addition of sugar to the grape must is allowed.

The traditional fermentation was by natural microflora, but cultivated yeasts, sold in a dried form, are now frequently used. Distillation must be by double-distillation in the directly fired Charentaise still, with a total capacity of ≤ 30 hL with a maximum working volume of 25 hL. In addition to the basic outline in Figure 1, many stills also have a wine heater through which the pipe from the swan's neck to the serpentine passes, thus preheating the next charge of wine. In the first distillation, a heads fraction is collected for recycle. In the second, heads and tails fractions are recycled. There is some variation in the recycle practices between distillers, but there is a restriction on the maximum strength of distillation, which must not exceed 72 vol % alcohol. All distillation must be complete by the

31st March after harvest, restricting the distillation period to about 5 months.

Maturation must be carried out in Limousin or Tronçais oak casks. As with other brandies and matured wine spirits, maturation was aided by the use of oak extracts, but this practice is becoming less common in Cognac. The French regulations prohibit the use of additives in the final product, other than water and sugar or caramel and restrict the minimum strength to 40 vol % alcohol [6], [32].

4. World Production Figures

It is difficult to be exact in estimating the quantitiy of spirit drinks produced throughout the

world, because of the prolific number of minor categories and local products, as well as the general lack of data for many markets. In addition, there is a time lag between new spirit distillation and final product packaging with aged drinks. The consumption figures listed below are compiled within these limitations. On this basis, the total world production of distilled spirit was ca. 5.8×10^9 L of 100 vol % alcohol in 1992.

Estimated spirit drinks consumption in 1992 (in 10^6 L 100 % alcohol) was as follows:

Whiskies	
Scotch	275
Canadian	90
Japanese	90
US including bourbon	108
Irish	8
Others	68
Gins/Geneva	
Geneva	18
Gin	122
Rums	
Dark	60
Light	160
Vodka	830
Korn	32
Aquavit	6
Tequila	25
Wine Spirit/Brandy	
Cognac	40
Brandy	220
Eau de vie	25
Other miscellaneous categories	450
Local Spirits	
China	1300
Korea	420
Japan	230
South America	630
South East Asia	360
Africa and others	240

5. Taxation

Alcoholic beverages are taxed in many countries as a source of Government revenue, via excise taxes, and in some cases value-added and other taxes. Spirits are frequently taxed at higher levels than competing products, such as beers and wines. For example, in the United States, excise tax levels (1st January 1991) set the rate for spirits at $ 13.50 per US proof gallon (approximately $ 7.14 per liter of absolute alcohol), whereas the rate for wine was $ 1.07 per wine gallon (approximately $ 2.36 per liter of absolute alcohol for a wine of 12 vol % alcohol). In addition, in many countries imported spirits may face discriminatory taxation intended to protect domestic spirits and/or wines, or simply to minimize importation of luxury goods.

In the run-up to the EC Single Market, efforts were made to harmonize the excise duty throughout the European Community. However, at the start of 1993, the agreed levels were a compromise, rather than true harmonization. Wine had a zero minimum rating, whereas the minimum rate for beer was ECU 187. A minimum rate of ECU 550 was set for spirits, but existing rates between ECU 550 and ECU 1000 could not be reduced, whilst those above ECU 1000 could not be lowered below ECU 1000. The rates in the individual member states are listed in Table 1, highlighting the wide variation throughout the Community. There is a provision that the minimum rates will be reviewed at two-year intervals, but an unanimous decision is required to implement any change. It is therefore unlikely that the rates will be harmonized, at least in the short-term, on a basis of equality of taxation per unit of alcohol.

Table 1. Excise taxation rates in EC countries (1st January 1993) in ECU per hectoliter of 100 vol % alcohol

Country	Beer	Still Wine	Spirits
Belgium	328	318	1510
Denmark	1054	1253	3973
France	56	29	1124
Germany	130	0	1247
Greece	184	0	600
Ireland	2262	2422	2623
Italy	439	0	606
Luxembourg	100	130	904
Netherlands	389	327	1381
Portugal	273	0	682
Spain	78	0	564
United Kingdom	1555	1607	2780

6. Legislation

Legislative requirements vary and only the most basic guidance is given here. In many countries alcoholic beverages are included with other food and drink and must meet local food laws. There is a growing need for a quality system based on HACCP (Hazard Analysis and Critical Control Points), organized, documented, and managed to ISO 9000 standard. Regional and national definitions must also be met. Some of the

requirements are outlined in Chapter 2, but definitions also extend to packaging and labeling. For example, minimum strengths for individual categories are laid down in the EC Spirit Drinks Regulations [7], but national laws may stipulate higher values. For example, in France the minimum strength for cognac is 40 vol % alcohol, whereas the EC minimum for wine spirits is 37.5 vol %. Besides the consumer protection of weights and measures legislation, there are often prescribed bar measures and packaging volumes (e.g., the standard bottle size in the EC is now 70 cL) but a range of other volumes are also prescribed.

Labeling must be such that correct category names are used and that other information is correct. Stated age is usually that of the youngest spirit, although exceptions may be made where traditional solera systems are used, in which blending of old and young spirits is carried out during aging. Specific terms, associated with aged spirits, may only be used if the product complies with the appropriate regulations; e.g., for wine spirits in the EC, the terms VS, VSOP, and XO denote a minimum aging period of 3, 4, and 6 years, respectively. In many countries, the label should denote the actual volume and alcoholic strength of the product. In future, this may be extended to include a list of ingredients, which is already required in a few markets. Health warnings, regarding dangers of excessive consumption and risks to unborn children, are mandatory in the United States.

Some definitions limit the content of naturally occurring compounds which are potential health risks, such as methanol in fruit-derived spirits and hydrocyanic acid in stone-fruit spirits [7]. Some countries have additional limits for other naturally occurring compounds, such as nitrosamines in malt-derived spirits and urethane. Specific legislation may also exist for contaminants such as heavy metals. For example, the UK limit for lead in most spirits is 0.2 ppm compared with the general food limit of 1 ppm. The final product is also subject to consumer protection legislation.

7. Analysis

The primary measurements of the quality of spirit drinks are aroma, taste, and visual appearance. The use of nosing panels and sophisticated statistical analysis of their sensory comments, has been helpful in flavor and marketing research, but may be cumbersome for routine quality control [33], [34]. Chemical and physical analytical measurements supplement the traditional organoleptic quality judgements. Gas and liquid chromatography have been of great use in identifying many of the aroma compounds in distilled beverages, and more than 1000 are now known [35].

In 1992, the EC approved methods of analysis for neutral spirit [36], [37], and methods relevant to specific spirit drinks are planned. Elsewhere, particularly in North America, the AOAC Official Methods of Analysis are the basis of most methods [38].

Alcohol is measured by hydrometers, pycnometers, and density meters. Gas chromatography can be quite precise, but is not accepted by many excise authorities. Products containing high levels of dissolved solids, which can obscure direct alcohol measurement, must be distilled prior to analysis.

Color and clarity are measured in the EC neutral spirit methods by visual comparison with a water standard. In other spirits, color is determined by spectrophotometry at 430 or 525 nm. Clarity is measured in a nephelometer against a silicate standard.

Certain metals may be measured by traditional wet chemical methods, as are other ions, but atomic absorption spectrophotometry is the preferred method in well-equipped laboratories.

In neutral spirits, the permanganate clearing time is a general measure of the absence of impurities such as aldehydes. It is determined by monitoring the time taken for the color of the sample, after addition of potassium permanganate, to match a color standard. Aldehydes are measured, as acetaldehyde, by comparing the color formation after addition of Schiff's reagent. Higher alcohols, expressed as 2-methylpropan-1-ol, are determined by measuring the color formation after reacting the sample with an aromatic aldehyde, such as salicylaldehyde or *p*-dimethylaminobenzaldehyde, in hot dilute sulfuric acid. Acidity is determined by titration against sodium hydroxide. Esters, expressed as ethyl acetate, are determined by measuring color complexes at 525 nm after reacting the neutral spirit with hydroxylamine hydrochloride in al-

kaline solution, followed by iron(III) ions in acid solution. Methanol is measured by gas chromatography (GC) [36], [37].

Although GC methods are not precise enough to measure the low levels of higher alcohols and esters found in neutral spirits, they are the preferred and most accurate method for the determination of volatiles such as higher alcohols, aldehydes, esters, and fatty acids in other distillates. Traditional wet chemical methods can underestimate the total higher alcohol concentration because they do not detect *n*-propanol. In highly-flavored spirit, GC methods can give a truer measure of ester content, as many are of higher molecular mass than the ethyl acetate standard used in wet-chemical methods. Volatile compounds derived from fruits and other botanicals, such as terpenes, can also be measured by GC methods. However, products containing high levels of nonvolatile materials, such as sugars, require prior distillation [38].

GC coupled to sophisticated detectors, such thermal energy analyzers (TEA) or mass spectrophotometers is essential for the detection of trace compounds such as nitrosamines and urethane [38]. Liquid chromatography is now used for measuring sugars and other less-volatile materials, such as vanillin and other lignin-breakdown products in aged spirits. Carbon-14 measurement by scintillation counters is used to authenticate ethanol of fermentation origin as opposed to that derived from fossil fuels [36], [37].

1. Introduction

Microscopic stains are used for distinguishing visually between different cellular and tissue components in animal and plant material. Optical differentiation of this type is essential for the detection and accurate identification of cellular and tissue elements. Microscopic stains are most widely used in histology, cytology, and microbiology, but they are also valuable in the examination of textile fibers, paper, and other industrial products, as well as in unusual assignments like distinguishing individual paint layers in a work of art.

2. Historical Survey

At least one important microscopic stain, carmine, was employed for dyeing textiles in the days of ancient Rome and Greece. The substance was isolated from insects (*Coccus ilicus* and *C. cacti*) and prepared for use by heating with various salts (e.g., alum). Carminic acid is the actual coloring constituent of carmine. As early as 1770 carmine was utilized by HILL for microscopic purposes, and EHRENBERG (1838) later used it in the examination of protozoa. HARTIG (1854) employed carmine to highlight various parts of plants. VON GERLACH (1858) employed an ammoniacal carmine solution to demonstrate animal blood vessels, and in the process he discovered that various cellular elements had different affinities for the dye. The first modern histological stain, one that is still important today, was an extract of campeachy wood *(Haematoxylon campechianum)* – hematoxylin. BÖHMER (1865) developed a procedure for increasing the staining potential of hematoxylin with the help of alum, which acts as a mordant. Other early stains that are still employed include the alum hematoxylins of DELAFIELD (1885), EHRLICH (1886), MAYER (1891), and HARRIS (1900); the iron hematoxylins of WEIGERT (1892), BENDA (1886), and HEIDENHAIN (1892); and MALLORY's (1891) hematoxylin solution with phosphomolybdic acid.

The first synthetic aniline dye, aniline black, was prepared by RUNGE (1834). In the years that followed, many new aniline dyes were synthesized, some of which are still used for microscopic purposes. BÖTTCHER (1869) introduced the principle of differentiation with alcohol after staining with carmine or rosaniline. FISCHER (1876) used aqueous and especially alcoholic solutions of eosin for staining various tissues. Between 1875 and 1880, numerous new, more complex aniline dyes (e.g., triphenylmethane dyes) were employed for double staining. EHRLICH (1879) first classified dyes as acid or basic, showing that these differed in both their chemical properties and their histological applications. An extensive study of the oxidation products of

10.1002/14356007.a24_567

methylene blue was carried out by BERNTHSEN (1885).

The first trichrome staining method for connective tissue was developed by VAN GIESON (1889). This was followed by the introduction of many important staining methods, including the use of methylene blue (UNNA, 1891), triple staining (FLEMMING, 1891. BENDA, 1891), methyl green – pyronin (PAPPENHEIM, 1899), and Sudan III (DADDI, 1896). Between 1875 and 1895, fundamental cytological phenomena were discovered and described with the help of staining (e.g., mitosis, cell maturation, and fertilization). At first, fixation and staining were carried out as a single step, but the introduction of thin sections made it necessary to perform fixation separately. A mixture of osmic/chromic acid (FLESCH, 1879) or osmic/acetic acid (FLEMMING, 1882) was used as a fixative, permitting very effective demonstration and preservation of cell structures. Triple aniline staining (e.g., with safranine, gentian violet, and orange G), described by FLEMMING (1891), was introduced to cytology and histology in the 1890s.

A new class of dyes – the phthalocyanines– was developed in 1907. These also belong to the category of acid and basic dyes. A particularly well-known member of the group is alcian blue 8GX. Apart from slight alterations, the staining techniques of ROMANOWSKY (1891), JENNER (1890), LEISHMAN (1901), WRIGHT (1901), MAY – GRÜNWALD (1902), and GIEMSA (1902) are still employed today. All involve methylene blue, its oxidation products, and eosin in various combinations. PAPPENHEIM (1912) utilized the MAY-GRÜNWALD solution and subsequently the GIEMSA solution in "universal panoptic staining". Solutions of methylene blue and eosinate were also perfectly suited for the identification of parasites in blood. WITTEKIND (1976) found that azure B is the true coloring constituent of polychrome methylene blue, which consists of a mixture of methylene blue, azure A, B, and C, and thionin.

Attempts to stain living material were described as early as the seventeenth century. The first experiments were conducted with the naked eye, initially with insoluble colored substances and later with staining solutions (e.g., saffron, methylene blue, and neutral red). The development of colloidal acid dyes (e.g., trypan red, trypan blue, and Evans blue) early in the twentieth century led to the introduction of vital staining. This method has been used to study, for example, tissue cultures, cells in flowing blood, and nerve tissue.

CONN (1941) developed a completely new staining method for the localization of antigens using labeled antibodies. Diagnostic use of this method became possible after the discovery of special fluorescent dyes (e.g., fluorescein isothiocyanate, FITC) and ways to bind them to antisera. The binding of antibodies to horseradish peroxidase represented another remarkable step forward, because this enzyme can be visualized after it has been coupled to antigens present in a tissue (NAKANEU; PIERCE, 1967).

3. Characteristics of Microscopic Stains

A microscopic stain is a colored compound that is capable of binding to a substrate (see Table 1). Depending on the number of stains used, a distinction can be made between *simple* and *multiple* staining. Multiple staining is divided in turn into *successive* and *simultaneous* staining, depending on the manner in which the stains are applied. An other useful distinction is that between *diffuse* and *selective* staining. In contrast to diffuse staining, selective staining involves exclusive or especially conspicuous coloration of particular components. Frequently, the staining process involves such a high degree of chemical specificity that the stain can be used as a histochemical reagent.

Stains are called *metachromatic* if they induce in certain constituents of the substrate a color different from that of the stain itself. In *orthochromatic* staining, the shade of the colored tissue is identical to that of the staining solution. Metachromasia is based on a shift in the absorption wavelength of a stain as a consequence of its binding to the substrate with concurrent formation of oligomers of the stain ("absorption units"). Thiazines, oxazines, azines, and xanthenes are among the dyes that exhibit metachromatic effects.

Two characteristic groups of atoms can be differentiated within a stain molecule: the *chromophore* and the *auxochrome*. Chromophoric

Table 1. Microscopic stains in biology and medicine

Dye (Colour Index no.)	CAS registry no.	Principal uses
Acridine dyes		
Acridine orange (C.I. 46 005)	[*10127-02-3*]	fluorescent staining of DNA and RNA (differential stain) for flow cytometry, supravital staining in cytology
Acriflavine	[*8048-52-0*]	fluorescent stain for aldehydes (pseudo-Schiff reagent)
Anthraquinone dyes		
Alizarin red S (C.I. 58 005)	[*130-22-3*]	embryonic bone (fetal ossification), calcium, bone
Carmine (C.I. 75 470)	[*1390-65-4*]	chromatin (mainly as borax carmine), glycogen (Best's stain)
Carminic acid (C.I. 75 470)	[*1260-17-9*]	chromatin
Nuclear fast red (C.I. 60 760)	[*6409-77-4*]	chromatin (as aluminum lake)
Arylmethane and diarylmethane dyes		
Auramine O (C.I. 41 000)	[*2465-27-2*]	fluorescent staining of acid-fast bacteria, fluorochrome Schiff's reagent
Triarylmethane dyes		
Anionic		
Acid fuchsin (C.I. 42 685)	[*3244-88-0*]	connective tissue (van Gieson's, Cason's, Mallory's stain)
Brilliant blue R (C.I. 42 660)	[*6104-59-2*]	stoichiometric staining of proteins
Fast green FCF (C.I. 42053)	[*2353-45-9*]	cyptoplasmic counterstain (Papanicolaous's stain), nuclear histone proteins, arginine-rich sites
Light green SF (C.I. 42 095)	[*5141-20-8*]	cytoplasmic counterstain (Papanicolaou's stain), nuclear histone proteins, arginine-rich sites
Cationic		
Brilliant green (C.I. 42 040)	[*633-03-4*]	bacteria, components of culture media
Crystal violet (C.I. 42 555)	[*548-62-9*]	bacteria (Gram's stain), chromatin, Holzer's stain for neuroglia
Malachite green (C.I. 42 000)	[*2437-29-8*]	bacteria and fungi, plant cell nuclei and pollen
Methyl green (C.I. 42 585)	[*7114-03-6*]	chromatin (DNA quantitatively), fungi, gonococci
New fuchsin (C.I. 42 520)	[*3248-91-7*]	Schiff's reagent (Feulgen and PAS reaction), bacteria (Ziehl – Neelsen), elastic fibers (resorcin – fuchsin stain)
Pararosaniline (C.I. 42 500)	[*6035-94-5*]	Schiff's reagent (Feulgen and PAS reaction), elastic fibers (aldehyde fuchsin), bacteria (Ziehl – Neelsen)
Rosaniline (C.I. 42 510)	[*632-99-5*]	Schiff's reagent (Feulgen and PAS reaction), bacteria (Ziehl – Neelsen)
Victoria blue B (C.I. 44 045)	[*2580-56-5*]	chromatin (used in cytology, histology, botany), glial fibers in neurohistology, bacteria, elastic fibers
Azine dyes		
Azocarmine B (C.I. 50 090)	[*25360-72-9*]	connective tissue (azan stain)
Janus green B (C.I. 11 050)	[*2869-83-2*]	supravital stain for mitochondria
Azo dyes		
Alizarin yellow GG (C.I. 14 025)	[*584-42-9*]	indicator in bacterial media
Biebrich scarlet (C.I. 26 905)	[*4196-99-0*]	connective tissue (in trichrome stains), nuclear histone proteins, arginine-rich sites
Evans blue (C.I. 23 860)	[*314-13-6*]	vital stain for tumor cells, retrograde staining of axons
Orange II (C.I. 15 510)	[*633-96-5*]	cytoplasmic counterstain in histology
Orange G (C.I. 16 230)	[*1936-15-8*]	cytoplasmic counterstain in many techniques, keratin
Congo red (C.I. 22 120)	[*573-58-0*]	amyloid, cytoplasmic counterstain
Trypan blue (C.I. 23 850)	[*72-57-1*]	vital staining of cytoplasm
Bismarck brown Y (C.I. 21 010)	[*10114-58-6*]	cytoplasmic counterstain (Papanicolaou's stain)
Oil red O (C.I. 26 125)	[*1320-06-5*]	lipids in histological material and in electrophoresis
Ponceau S (C.I. 27 195)	[*6226-79-5*]	connective tissue (in van Gieson's stain), gel electrophoresis
Sudan red 7 B (C.I. 26 050)	[*6368-72-5*]	lipids in histological material
Sudan black B (C.I. 26 150)	[*4197-25-5*]	fat in histological material, bacteria, Golgi apparatus
Benzimidazole dyes		
Hoechst 33 258	[*23491-44-3*]	fluorochrome for *q*-banding of chromosomes

Table 1. (Continued)

Diazonium salts		
Fast blue B (C.I. 37 235)	[*14263-94-6*]	α-naphthyl acetate in monocytes and *T* lymphocytes, coupled tetrazonium reaction for proteins
Fast blue RR (C.I. 37 155)	[*14726-29-5*]	coupling agent for enzymes (esterases and phosphatases)
Hydroxyketone dyes		
Hematoxylin (C.I. 75 290)	[*517-28-2*]	chromatin (most widely used stain for cell nuclei), applied as metal – complex stain with aluminum, iron, chromium
Indigo dyes		
Indigo carmine (C.I. 73 015)	[*860-22-0*]	cytoplasmic counterstain, connective tissue
Oxazine dyes		
Brilliant cresyl blue (C.I. 51 010)	[*81029-05-2*]	reticulocytes, Heinz bodies, chromatin
Celestine blue (C.I. 51 050)	[*1562-90-9*]	chromatin (substitute for hematoxylin)
Cresyl fast violet	[*10430-47-4*]	Nissl substance, Barr bodies

groups absorb light in the visible region of the spectrum and confer upon the stain its color, which represents the complementary color of the absorbed light. Typical chromophores are atomic groupings containing double bonds, such as C=O, C=S, C=N, N=N, N=O, NO_2, and various conjugated systems. The involvement of several adjacent chromophores is also common. Auxochromes deepen the color and fulfill the additional important function of binding the stain to the substrate. These substituents may be present either in ionized form or as neutral functionalities that are capable of forming covalent bonds with the substrate or coordinate bonds with a metal ion (*mordant*). Stains often contain several auxochromes. The counterions of auxochromes are usually H^+, Na^+, or Cl^-. Stains with positively charged auxochromes (e.g., primary, secondary, and tertiary amines) are called *basic* (better: *cationic*) stains. The *acid* or *anionic* stains contain negatively charged auxochromes (carboxylate, sulfonate, or phenolate groups). Stains with both anionic and cationic groups in the same chromophore, which are thus electrically neutral overall, are called *amphoteric*.

Organic compounds containing conjugated double-bond systems that form large, relatively rigid, planar structures are often capable of fluorescence. The nature of the linear arrangement and the presence of one or several substituents can significantly influence the fluorescent properties of such a stain.

In *progressive* staining, a substance is colored with a staining solution until a particular desired color intensity has been achieved. In *regressive* staining, the tissue is intentionally overstained, and excess stain is subsequently removed (e.g., by dissolving it in water, alcohol, or acidified alcohol) in a differentiation process.

In principle, true staining is achieved only after binding has occurred between the stain and the substrate. Physical factors that influence the staining process include the size of the dye particle, the porosity of the substrate, and diffusion effects. Many different types of physical and chemical linkage can develop between a stain and a substrate, ranging from adsorption to covalent bonding. The simplest form of staining is based on electrostatic attraction between oppositely charged ionized groups on the stain and the substrate, but numerous histochemical procedures result in the formation of covalently bound colored material derived from reactive groups in the stain and the tissue. Such a stain cannot easily be leached out. Van der Waals forces are involved in the direct staining of cellulose and elastin. Hydrophobic interactions are responsible for the penetration of oil-soluble stains into lipids, and for their retention in hydrophobic tissue. Metal ions (e.g., aluminum, iron, chromium, tungsten, molybdenum, and copper), known as *mordants*, are capable of forming stain – metal complexes with many stain molecules. Ring-shaped chelates often play an important role in such stain – metal complexes. A mordant can be applied prior to staining, mixed with the stain, or applied after staining. A complex that contains excess stain relative to mordant is called a *lake*, although most staining methods instead involve excess mordant (e.g., staining with iron or aluminum hematoxylin). The chief benefit

Table 1. (Continued)

Dye (Colour Index no.)	CAS registry no.	Principal uses
Cresyl violet acetate	[*10510-54-0*]	Nissl substance, chromatin, Heinz bodies
Gallocyanine (C.I. 51 030)	[*1562-85-2*]	Nissl granules, nucleic acids (quantitatively)
Nile blue A (C.I. 51 180)	[*3625-57-8*]	vital staining of transplanted tissue, lipids (after oxidation to Nile red)
Nile red	[*7385-67-3*]	lipid stain, fluorochrome in flow cytometry
Orcein	[*1400-62-0*]	connective tissue (elastic fibers) (Darrow's, Fraenkel's stain), HB_S-antigen in histology
Phenazine dyes		
Neutral red (C.I. 50 040)	[*553-24-2*]	vital stain for cytoplasmic organelles, bacteria, Nissl substance, chromatin (Twort's stain)
Safranine O (C.I. 50 240)	[*477-73-6*]	chromatin, bacteria (Gram's stain)
Phthalocyanine dyes		
Alcian blue (C.I. 74 240)	[*33864-99-2*]	glycosaminoglycans in histology
Luxol fast blue MBSN (C.I. 74 180)	[*1328-51-4*]	myelin sheaths in histology
Thiazine dyes		
Azure A (C.I. 52 005)	[*531-53-3*]	blood and bone marrow smears (constituent of polychrome methylene blue), reticulocytes
Azure B (C.I. 52 010)	[*531-55-5*]	blood and bone marrow smears (constituent of polychrome methylene blue), reticulocytes
Azure C (C.I. 52 002)	[*531-57-7*]	blood and bone marrow smears (constituent of polychrome methylene blue), reticulocytes
Methylene blue (C.I. 52 015)	[*61-73-4*]	blood and bone marrow smears (constituent of polychrome methylene blue), bacteria, vital staining of axons
New methylene blue N (C.I. 52 030)	[*6586-05-6*]	reticulocytes
Thionin (C.I. 52 000)	[*78338-22-4*]	Nissl granules, chromatin, metachromatic substances, Barr bodies, Feulgen reac- tion
Toluidine blue O (C.I. 52 040)	[*92-31-9*]	chromatin, metachromatic substances, Nissl substance
Thiazole dyes		
Thioflavin T (C.I. 49 005)	[*2390-54-7*]	fluorescent stain for viruses
Xanthene dyes		
Anionic		
Rose bengal (C.I. 45 440)	[*632-69-9*]	cytoplasmic counterstain, eosinophilic granules, bacteria
Eosin Y (C.I. 45 380)	[*548-26-5*]	cytoplasmic counterstain in many techniques, eosinophilic granules
Erythrosin B (C.I. 45 425)	[*568-63-8*]	cytoplasmic counterstain
Fluorescein isothiocyanate (C.I. 45 350 : 1)	[*3326-32-7*]	fluorescent antibody marker
Phloxine B (C.I. 45 410)	[*18472-87-2*]	cytoplasmic counterstain
Cationic		
Pyronin Y (C.I. 45 005)	[*92-32-0*]	RNA (quantitative) in combination with methyl green
Rhodamine B (C.I. 45 170)	[*81-88-9*]	fluorescent staining of lectins, fluorochrome for peroxidase, fluorochrome for bacteria
Chromogenic reagents		
Nitro blue tetrazolium	[*298-83-9*]	histochemical determination of dehydrogenases and alkaline phosphatase
Tetranitro blue tetrazolium	[*42798-98-1*]	histochemical determination of dehydrogenases

of histological staining with mordant stains is that colors developed in the tissue are not subject to extraction with water, alcohol, or weak acids, all of which are used in counterstaining, where counterstaining means that different cellular structures are stained different colors (e.g., cell nuclei blue and cytoplasm orange). Strong acids decolorize the tissue, an effect that can be exploited for differentiation purposes.

4. Nomenclature, Sources of Supply

Most dyes are referred to by trivial names that provide no insight into their chemical nature

or use. The third edition of the *Colour Index* [39], identifies dyes and other colored compounds by number, and describes their colors and fields of application. Natural dyes are listed separately. The trade name of a dye mixture typically reflects the dominant or most important constituent present. Few dyes are supplied as pure compounds; instead, they are mixed with inactive fillers, usually sodium chloride, and they frequently consist of more than one colored substance. Chromatographic and spectroscopic techniques are used to test the quality of a dye.

The Biological Stain Commission was founded in the United States in 1920 to certify samples of stains for quality and suitability in specific applications. Certified stains always carry a label stating the content, the Colour Index number, and the batch number. The criteria applied to industrial dye and stain standards, which also serve as a basis for DIN and National Committee for Clinical Laboratory Standards (NCCLS) specifications, are listed below.

Dyes:

1) Chemical definition: generic name, chemical name molecular structure, Colour Index (C.I) number, CAS registry number
2) Relative molecular mass of the dye molecule
3) Counterion of the dye
4) Wavelength (λ) or wavenumber (ν) of absorption maximum
5) Decadic molar extinction coefficient
6) Maximum water content of the batch
7) Absence of solvent
8) Impurities:
   Maximum content of inorganic impurities
   Maximum content of colored organic impurities (as determined by TLC and/or HPLC)
   Maximum content of colorless impurities

Stains:

1) Colored components (dyes) in the stain:
   Types of dyes present (including counterions)
   Dye concentrations
   Types and amounts of colored and colorless impurities
2) Concentration of inorganic salts
3) Chemical description of the solvent
4) pH of the stain (for aqueous solutions)
5) Stability of the stain (shelf-life, expiration date)

See Table 2 for physical and chemical properties of stains listed in Table 1.

The following manufacturers produce dyes for microscopic staining:

5. Classification of Biological Stains for Microscopy

Biological stains have traditionally been classified by their users as basic, acid, mordant, or oil-soluble. For summary lists of representative staining procedures, see Tables 3, 4, 5, 6.

5.1. Basic or Cationic Stains

Basic or cationic stains are used to stain nuclei and most of the anionic structural elements of the cytoplasm and extracellular space. The stains are applied in acidified solution that guarantees ionization of their primary, secondary, and tertiary amino groups. Cationic stains are capable of binding to three types of anions present in tissues: phosphate residues of nucleic acids, sulfate esters of various macromolecular carbohydrates, and carboxylate ions from carbohydrates and

Table 2. Physicochemical data for stains listed in Table (according to [13])∗

Dye	λ_{max}, nm	Formula	Mr	Color of stained entity
Acid fuchsin	546 (W)	$C_{20}H_{17}N_3Na_2O_9S_3$	585.55	magenta
Acridine orange	489 (W)	$C_{17}H_{19}N_3$	369.94	yellow-orange (f)
Acriflavine	462 (M)	$C_{14}H_{14}N_3$	330.81	yellow (f)
Alcian blue 8GX	615 (W)	$C_{56}H_{68}Cl_4CuN_{16}S_4$	1298.88	blue

proteins. The dissociation of carboxylic acids is suppressed in solutions with high concentrations of hydrogen ions, whereas sulfate groups ionize even in strongly acidic medium. A suitable acid of moderate strength is phosphoric acid. A basic protein such as hemoglobin contains an excess of free amino groups relative to carboxyl groups. For this reason, carboxyl groups in such a protein bind cationic stains only in alkaline solution. The staining properties of cationic stains are thus influenced in a fundamental way by the pH of the solution: in acidic solution, only structures rich in sulfated carbohydrates are stained, but all structures are stained in neutral or alkaline solution. In their principal application (i.e., nuclear staining), cationic stains are used in dilute aqueous solution (0.1 – 0.5 %) acidified to pH 3 – 5.5 with glacial acetic acid or a suitable buffer.

Structures susceptible to cationic stains in acidic solution are called *basophilic*. When nuclei are stained with cationic dyes, basophilia is clearly apparent at sites of accumulation of cytoplasmic RNA (e.g., Nissl bodies in the neurons) and in structures that contain sulfated carbohydrates (e.g., mast cell granules, cartilage matrix, and many secretory products). Cationic stains do not stain the nucleus specifically.

The following stains can be used for both nuclear staining and counterstaining: toluidine blue (C.I. 52 040), neutral red (C.I. 50 040), methyl green (C.I. 42 585), and polychrome methylene blue. In alkaline or neutral solution cationic stains facilitate rapid, one-step survey staining.

Differential staining of DNA (blue-green with methyl green) and RNA (pink to red with pyronin Y) can be accomplished by simultaneous application of the two cationic stains methyl green and pyronin Y (C.I. 45 005). The selectivity of staining is a function of the structures of the stains and their associated staining kinetics. Alcian blue 8GS, 8GX, or 8GN (C.I. 74 240) can be used at pH 2.5 to demonstrate acidic muco substances. The advantage of using alcian blue in carbohydrate histochemistry is that this dye does not stain nuclei or cytoplasmic deposits of RNA in sections.

Cationic stains are also important for bacteriological staining. Crystal violet (C.I. 42 555) is utilized in various histological and cytological staining methods, and it is also employed in the gram technique. In this technique, bacterial cells are first stained with crystal violet, then treated with the mordant iodine, and finally counterstained (e.g., with safranin), a procedure that permits a distinction to be made between gram-positive (dark blue) and gram-negative (red) organisms. Basic fuchsin (pararosaniline, C.I. 42 500), a well-known histological dye used in the periodic acid Schiff (PAS) reaction in Feulgen staining and the Gomori aldehyde – fuchsin method, is also employed in the detection of various mycobacteria. Cell material in this case is stained with a phenolic solution of fuchsin and counterstained with methylene blue. Acid-fast rods appear bright red against the blue-stained background material.

Cationic stains such as acridine orange (C.I. 46 005) and oxazines can act as *fluorochromes.* Both living and fixed cells absorb these stains from dilute solutions. Acridine orange is used in supravital fluorescent staining, fluorescent stain-

Table 3. Staining procedures in cytology and histology

Specimen	Fixation	Staining technique (substrate)	Dyes and stains used
Cytology			
General cytology (smears, imprints, serous effusions)	wet fix: ethanol spray	Papanicolaou, H & E *	aluminum hematein, eosin Y, fast green FCF, Bismarck brown Y, orange G
	air dry: methanol	H & E,∗ Giemsa	for Giemsa see below
Blood and bone marrow smears	air dry: methanol	Standard Giemsa, May – Grünwald – Giemsa	azure B, eosin Y, azure A, B, C, methylene blue, eosin Y
Histology			
Cell nuclei	formaldehyde	Mayer's or Harris's hematein	aluminum hematein (eosin Y as counterstain)
	formaldehyde	Domagk	nuclear fast red, aniline blue
	formaldehyde	Twort	neutral red, fast green
Cytoplasmic organelles			
Mitochondria	formaldehyde – $CaCl_2$ (Baker)	Heidenhain	iron hematein
Lysosomes	formaldehyde	hexazonium – pararosaniline	pararosaniline
Endoplasmic	formaldehyde	Nissl	thionin

Neuroglia	formaledehyde	Holzer	crystal violet

∗ H & E = hematoxylin – eosin.

ing in exfoliative cytology, and in the staining of nucleic acids. Differentiation of the nucleic acids (DNA green, RNA red) can also be achieved with acridine orange. Another cationic fluorochrome, atebrin (no C.I. number), exhibits green fluorescence. It is used in the staining of mitotic chromosomes, in the demonstration of Y chromatin in interphase nuclei, and for blood components and blood protozoa.

5.2. Acid or Anionic Stains

Acid or anionic stains indicate positively charged cytoplasmic and extracellular material. Anionic stains are also used in acidic solution. Most tissue structures are stained nonspecifically if anionic stains are used alone. Histological counterstaining is one of the most frequent applications of anionic stains, the most common stain being eosin (eosin Y, C.I. 45 380,

Lipids	formalin	Smith	Nile blue A
DNA	intravital	Pearse	acridine orange
Mitochondria	intravital		acridine orange
Fungi	intravital		acridine orange
Mycobacterium tuberculosis	heat	Truant	auramine O – rhodamine B

eosin B, C.I. 45 400). Eosin is bound to the substrate by ionized cationic groups of proteins–usually an amino group of lysine or a guanidino group of arginine, amino acids that are present in almost all proteins. Differential staining effects are achieved only if two or more stains are applied either simultaneously or consecutively. For example, in a mixture of methylene blue and eosin, nuclei, cartilage, and collagen are stained blue, while the cytoplasm is stained red by the eosin. The various techniques available for staining collagen utilize mixtures of stains drawn from one or two stain groups. A mixture of two anionic stains is employed in van Gieson staining: one colors collagen and the other the cytoplasm, as well as muscle fibers and erythrocytes. In trichrome staining, two, three, or (less often) four anionic stains are applied in conjunction with phosphoric or phosphomolybdic acid. This causes collagen, cytoplasm, and erythrocytes all to be stained differently. Elements such as cartilage, fibrin, and secretory granules also acquire characteristic colors. Anionic stains used for marking collagen can also be empolyed to some extent in staining polysaccharides. Neutral polysaccharides, such as glycogen, may be revealed by staining according to the Best's carmine technique. Amyloid can be stained with Congo red (C.I. 22 120) and other direct techniques. Congo red is also capable of simultaneously staining amyloid and hydrophobic constituents (e.g., elastic fibers). Elastin is normally stained only slightly with anionic stains (e.g., eosin) but strongly with compounds such as orcein [C.I. (1st ed.) 1242] or aldehyde fuchsin.

Examples of common anionic stains are orange G (C.I. 16 230) and metanil yellow (C.I. 13 065). These azo dyes are used in combination with other anionic stains to stain cytoplasm. Biebrich scarlet (C.I. 26 905), another azo dye, has many applications (e.g., counterstaining, collagen staining, or selective protein staining in alkaline solution).

5.3. Mordant Stains

Mordant stains are used primarily in the staining of nuclei. Well-known representatives of this group are the natural dyes hematein and brazilein, which are derived from hematoxylin (C.I. 75 290) and brazilin (C.I. 75 280), respectively, by oxidation. Hematein is the active component of hematoxylin, and is formed by partial oxidation, also called maturation. Oxidation can take place either slowly through contact with atmospheric oxygen or by addition of an oxidizing agent. Hematein staining involves the use of aluminum or iron as a mordant.

Staining is partially prevented by chemical blockage from lysine and arginine residues. For good nuclear staining it is essential that the acidified solution contains more metal ions than hematein. Although both progressive and regressive staining are possible with aluminum hematoxylin, only progressive staining is appropriate with iron hematoxylin (e.g., Weigert's hematoxylin). In histochemical and other special staining techniques it is preferable that the nucleus is stained red. This can be done with an aluminum mordant and carminic acid (carmalum), aluminum mordant and brazilein (brazalum), or aluminum mordant and nuclear fast red (C.I. 75 470).

5.4. Oil-Soluble Stains

Oil-soluble stains (*lipochromes*) are used for demonstrating the presence of fats and lipids. Colored, nonpolar compounds dissolve in tissue and cellular lipids, causing them to become microscopically visible. Fat stains are effective for coloring lipids because they are more soluble in the lipids than in their solvents. The first soluble stains used for the coloration of fats were Sudan III (C.I. 26 100), Sudan IV (C.I. 26 105), and oil red O (C.I. 26 125). These stains dissolve in hydrophobic fats that are liquid at the temperature at which staining is carried out. Sudan black B (C.I. 26 150) is a suitable stain for all lipids. Lipochromes dissolve in lipids only at temperatures above the lipid melting point. Lipids containing unsaturated fatty acids melt above 60 °C, so preliminary treatment with bromine water is required prior to staining with Sudan black B. Certain lipoproteins in which the lipids are "masked" by proteins must be subjected to acid hydrolysis before staining.

5.5. Chromogenic Reactions

The most important chromogenic reactions are the Feulgen reaction for staining nuclear DNA

and the periodic acid Schiff (PAS) reaction for staining of tissue polyssaccharides.

With both techniques aldehyde groups are stained which are released by acid hydrolysis of DNA in case of the Feulgen reaction and by the oxidation of polyssaccharides for PAS. Both procedures use the Schiff reagent which is an aqueous solution of basic fuchsin or pararosanilin.

A standard feulgen protocol for reproducible quantitative staining of DNA for image cytometry has been recommend by the European Society for Analytical Cellular Pathology, ESACP [43–48]

6. Enzyme Histochemical Reactions

An enzyme is a protein that functions as a catalyst. Catalysis is triggered by the binding of an enzyme molecule to a molecule of one of the reactants, which acts as substrate. The substrate may be either a neutral organic compound or an ion. An important feature of enzymatic catalysis is that it proceeds at room temperature and approximately neutral pH. Various histochemical methods for staining enzymes are used in conjunction with blood and bone marrow smears to identify normal and abnormal leukocytes, and for differential staining of B and T lymphocytes. Enzymes display high specificity for their substrates and for the particular reactions they catalyze. For example, phosphatases catalyze the hydrolysis of esters of phosphoric acid. *Acid phosphatases* are typical lysosomal constituents, and can be demonstrated in the cells of kidney tubules and the prostate gland, as well as in phagocytes and degenerated cells. *Alkaline phosphatases* are present in the cytoplasm of leukocytes (neutrophils and basophils) and their precursors, but not in myeloblasts. In myeloid leukemias, the abnormal circulating leukocytes contain little or no alkaline phosphatase. The fact that this enzyme catalyzes hydrolysis of the phosphate of β-hydroxynaphthoic anilide (Naphthol AS) at high pH is utilized for its detection. The Naphthol AS molecule that is released couples immediately with a diazonium salt present in the incubation medium, giving rise to an insoluble azo dye.

Various *esterases* that catalyze the hydrolysis of α-naphthyl acetate can also be detected histochemically. These are present in both monocytes and T cells. The enzymes themselves are quite heat resistant and can be detected in material even after fixation. In this technique the α-naphthol formed on hydrolysis is coupled with diazotized pararosaniline. The final product is a stain composed of one pararosaniline molecule and three molecules of α-naphthol.

Dehydrogenases are detected by histochemical reactions with various tetrazolium salts. Tetrazolium salts are heterocyclic compounds that are converted to insoluble, colored formazans by reduction. The most frequently used reagent is nitro blue tetrazolium chloride (nitro BT); the resulting formazan is insoluble in fats and can bind to proteins.

Peroxidases catalyze the oxidation of various substances by hydrogen peroxide, including reduced coenzymes, fatty acids, amino acids, reduced cytochromes, and many other compounds. This reaction leads to an oxidized donor and two water molecules starting from a donor molecule and a molecule of hydrogen peroxide. Many organic compounds (e.g., amines, phenols, and the leuco compounds of dyes) can serve as donors. Peroxidase activity can be detected in the granules of myeloid leukocytes, in various neurons, and in secretory cells. The peroxidase histochemical method is based on the catalytic reaction between hydrogen peroxide and substances that yield insoluble products after oxidation. One of the oldest techniques utilizes benzidine as the donor, which is introduced along with hydrogen peroxide into the incubation medium, causing the benzidine to be oxidized to a blue substance. The most commonly used donor today is 3,3′-diaminobenzidine tetrahydrochloride (DAB). Spontaneous oxidation of this amine is very limited, but an insoluble, amorphous, brown substance is formed rapidly in the presence of peroxidase. This unstable substance reacts immediately with more DAB to form polymers containing the quinone and indamine chromophores. The reaction can be made more sensitive by substituting tetramethylbenzidine (TMB) as the donor, which leads to a blue product. The activities of certain enzymes (e.g., cytochrome oxidase and catalase) can be responsible for false positive results in the histochemical peroxidase reaction.

7. Immunohistochemical Staining Methods

The objective of immunohistochemical techniques is the detection and identification of antigens in cells and tissue sections by means of specific antibodies. Both *monoclonal* and *polyclonal* antibodies can be used for routine applications. Apart from appropriate specificity and low cross-reactivity, one of the main requirements for a suitable antibody is its ability to recognize antigens in tissues that have been fixed in formalin or embedded in paraffin. This requirement is frequently not met by antibodies against glycoproteins, which are diagnostically quite important. When antigen molecules encounter molecules of their antibodies, *antigen – antibody complexes* may be formed. The interaction of an antibody with its antigen can be revealed very specifically by suitable labeling of one of the reaction partners (e.g., with fluorescent dye or an enzyme). The detection of antibody that is bound to an antigen (*primary antibody*) can be accomplished in various ways, and by use of a marker coupled to the primary antibody either directly or indirectly through selected ligands. The function of the marker substance is to make the antigen – antibody complex visible. The most common marker system in immunohistochemical applications is horseradish peroxidase, which is susceptible to several histochemically stable, high-contrast color reactions. Thus, peroxidase in the presence of hydrogen peroxide is used to oxidize soluble, colorless chromogens to insoluble, colored end products.

In the *direct fluorescence antibody method*, labeled antibody is reacted with its tissue antigen, which is present in reactive form. Conditions are selected such that the antibody, which carries a fluorescent label, binds strongly only to the antigen. In *indirect* immunofluorescence, a fluorescent immunoglobulin is caused to react with specific antibodies as a way of detecting the presence of antigens in tissue. Fluorochromes used for these purposes include fluorescein isothiocyanate (FITC), tetramethylrhodamine isothiocyanate (TRITC), and lissamine rhodamine B 200 sulfonyl chloride (RB 200 SC). Excitation in the UV or blue region of the spectrum results in yellowish green (FITC) or red (TRITC or RB 200 SC) fluorescence.

The principle of the *direct enzyme labeling methods* is analogous to that of direct immunofluorescence. In this application enzymes are used as antibody markers in place of fluoro dyes. The enzymes employed are horseradish peroxidase, alkaline phosphatase, glucose oxidase, and galactosidase. The enzymes are developed with various substrates (chromogens) in such a way that differently colored products are formed, thereby revealing visually the presence of antigen – antibody complex and, consequently, a local immune response. In the case of peroxidase, the most frequently applied marker enzyme, the chromogens used are 3,3′-diaminobenzidine and 3-aminoethylcarbazole (AEC). DAB reacts with H_2O_2 to give a brown product that is insoluble in alcohol, whereas AEC gives a red, alcohol-soluble product. If alkaline phosphatase is used as the marker enzyme, the color reaction is produced, for example, by Naphthol AS MX phosphate together with fast red (red) or fast blue (blue). Enzymes can be coupled directly to antibodies (conjugates), or unconjugated methods can be applied, in which case the marker enzyme is fixed at the site of the antigen – antibody reaction through (antienzyme) antibodies. Conjugated methods are the easiest to carry out, but they have the disadvantage of lower sensitivity.

The indirect method is analogous to indirect immunofluorescence, in that it uses an enzyme as the marker. In the unconjugated antibody – enzyme-bridge method, a bridge-forming antibody is linked between an antibody directed against a particular marker enzyme and an unconjugated primary antibody directed against the antigen to be detected. The primary antibody and the antibody directed against the marker enzyme must originate from the same animal species, and the bridging antibody is also directed against immunoglobulins from this species. In order to detect the immune reaction (and antigen in the tissue), enzyme is added, this becomes bound by the enzyme antibody, and the combination is then detected histochemically.

A modification of the above method is the *enzyme – antienzyme complex technique*, in which antienzyme antibody and marker enzyme are added not successively, but in the form of a soluble enzyme – antienzyme complex. The peroxidase – antiperoxidase complex (PAP complex) and the alkaline

phosphatase – antialkalinephosphatase complex (APAAP complex) have proved particularly useful. The PAP complex is usually employed in the case of polyclonal antibodies from rabbit and goat, and the APAAP complex in monoclonal antibodies from mouse. With a monoclonal primary antibody of this type from mouse and an APAAP complex formed with monoclonal (mouse) antibodies against alkaline phosphatase, an antimouse immunoglobulin antibody is used as the bridging antibody. The concentration of the marker enzyme at the site of the antigen (hence the sensitivity of the test) can be increased by repeated incubation with the complex (multistep method).

The *(strept)avidin – biotin method* is based on the ability of the egg-white glycoprotein avidin to physically bind four molecules of the vitamin biotin. Avidin, which is isolated from chicken egg whites, can be replaced by streptavidin, a protein produced by *Streptomyces avidinii*. As in the PAP or APAAP method described above, three reagents are required. The first is the primary antibody, directed specifically against the antigen to be determined. Next is a secondary antibody, which can bind to the first, and this is conjugated with biotin. The third reagent is either an enzyme coupled to (strept)avidin or a preformed (strept)avidin – biotin – peroxidase complex. Free sites on the avidin molecule permit binding between the biotin and the secondary antibody. The enzyme (and therefore the desired antigen) is made visible with a suitable chromogen. Since several complexes can bind to a single avidin molecule, it is possible to increase the peroxidase concentration at the antigen site, thereby increasing the sensitivity of the method.

1. Native Starch

Starch [*9005-25-8*], the principal source of dietary calories to the world's human population, has many chemical and physical characteristics that set it apart from other food components and give it numerous applications. Food processors and other industrial users should be familiar with starch's structural and behavioral characteristics so as to make use of its properties. The chemistry and technology of starch has been reviewed in detail [1].

Unlike other carbohydrates and edible polymers, starch occurs as discrete particles called starch granules. These particles are unique to the plant source and, therefore, starch from every plant type is different in appearance, properties, and particle size distribution. The size distribution of wheat starch granules during endosperm development has been reported [2]. Microscopists can readily identify the plant source of most commercial starches.

Starch in granular form is generally composed of two types of molecules, amylose and amylopectin. *Amylose* [*9005-82-7*] is a predominantly linear (1,4)-α-D-glucan (Fig. 1), some amyloses possessing a few 1,6 branches. *Amylopectin* [*9037-22-3*] (Fig. 2) is a branched, bushlike structure containing both (1,4)-α-D linkages between D-glucose residues and (1,6)-α-D branch points. Normal starches contain ca. 75 % amylopectin molecules. Amylopectin is a much larger molecule than amylose as shown in Table 1. It is these characteristic molecular sizes, amylose – amylopectin ratios, and granular structures which give each type of starch its unique properties.

Table 1. Physicochemical properties of amylose and amylopectin

Property	Amylose	Amylopectin
Molecular mass	50 00 – 200 000	one to several million
Glycosidic linkages	mainly (1,4)-α-D-	(1,4)-α-D-, (1,6)-α-D-
Susceptibility to retrogradation	high	low
Products of action of β-amylase	maltose	maltose, β-limit dextrin
Products of action of glucoamylase	D-glucose	D-glucose
Molecular shape	essentially linear	bush-shaped

Figure 1. Representative structure of linear amylose

Figure 2. Representative structure of amylopectin, including (1,6)-α-D branch point

1.1. Raw Materials [1, 3 – 5]

Plants grown for starch production include corn, sorghum, wheat, rice, tapioca, arrowroot, sago, and potato. Other noncommercial sources of starch include quinoa and amaranth, whose starches have been isolated and examined with respect to chemical and physical characteristics and possible uses [6 – 9].

1.2. Molecular Structure and Composition

The molecular structure and composition of amylose, amylopectin, and starch granules is largely described in Sections 1, 1.3.2, 1.4.1, 1.4.4, and 1.5 as well as Tables 1–4. Purified amylose forms strong, transparent films and fibers, having properties similar to cellulose [*9004-34-6*], except for the greater swellability of amylose and its alkaline solubility. Amylose molecules have degrees of polymerization (DP) of 350 – 1000 compared to amylopectin which has a DP of several thousand.

Table 2. Diameter and gelatinization temperature of starch granules

Source	Mean diameter, µm	Gelatinization temperature, °C
Corn	15	62 – 71
Wheat	20 – 22	53 – 64
Rice	5	65 – 73
White potato	33	62 – 68
Sweet potato	25 – 50	82 – 83
Tapioca	20	59 – 70

1.3. Biosynthesis and Structure

1.3.1. Biosynthesis of Amylose, Amylopectin and Involved Enzymes

Normal starch, containing both amylose and amylopectin, is biosynthesized by two enzymes, a *chain-lengthening enzyme,* which is apparently identical for both amylose and the linear portions of amylopectin chains, and a *branching enzyme* that gives rise to amylopectin. Evidence suggests that a branching enzyme requires an amylose chain of ca. 35 – 40 units before it can transfer a portion of that chain to form a branch on another starch molecule.

When starch granules are examined under normal light or by scanning electron microscopy, growth rings are visible around the hilum (see below) which may become wider in successive layers as the granule grows. Some evidence points to the beginning of amylopectin molecules at an inner lamella edge and extending to the outer edge.

1.3.2. Structure of the Starch Granule

Individual starch molecules that are formed by the action of starch synthetase nucleate at a point called the *hilum* (the botanical center of the granule). These starch molecules are produced and deposited in a radial, spherocrystalline arrangement. Synthetase enzymes cling to the surface of

starch granules although there is no membrane. The surface consists of end units of starch molecular chains deposited side-by-side during granular growth. Linear amylose molecules occur interspersed among the branched amylopectin molecules. Linear amylose molecules tend to form helices which are often double. The amylopectin molecules are thought to exist in a so-called "tassel-on-a-string" structure (see Fig. 3) [10 – 14]. In this structure short chains of 12 – 15 D-glucopyranosyl units occur about every 25 units of the main chain, which may consist of more than a thousand D-glucopyranosyl units.

Figure 3. Tassel-on-a-string model of amylopectin (ϕ = reducing end group)

The spherocrystalline radial arrangement of starch molecules in the granule is inferred from the Maltese cross that is seen on microscopic examination of starch granules under polarized light [1] (see Fig. 4). The center of the cross is at the hilum. X-Ray patterns of starch granules show that cereal starches possess an *A pattern*, which indicates chains of amylose or outer chains of amylopectin in antiparallel double helices separated by interstitial water. Tuber and root starches produce *B patterns,* with up to 30 % water present in sheets and columns. Legume starches possess C X-ray patterns, which are a mixture of A and B patterns. These patterns result primarily from the otherwise uncomplexed amylose molecules or long outer chains of amylopectin. Amylopectin molecules seem to be oriented with their reducing ends interior to the granule, as would be expected from outward biosynthetic growth. In addition to X-ray evidence, crystallinity is also evident from measurements by differential scanning calorimetry. This method measures the energy for melting crystalline regions when heated [15].

Figure 4. Micrograph of potato starch in polarized light (magnification ca. ×250)

1.4. Physicochemical Properties

Undamaged starch granules are insoluble in cold water, but can reversibly absorb water and swell when their aqueous dispersion is heated. In water at 25 °C, the percentage increase in granule diameter ranges from 9.1 % for normal (native) corn starch to 22.7 % for waxy (≈100 % amylopectin) corn starch. As temperature is increased, the molecules in the starch granule vibrate vigorously, breaking intermolecular bonds, thus allowing increased interaction with water molecules. This penetration of water combined with the increased separation of the starch chains increases randomness and decreases crystallinity in the granule. Continued heating in the presence of free water results in complete loss of crystallinity, as evident by loss of birefringence of the starch granules and changes in the X-ray diffraction pattern. The temperature range over which birefringence disappears is called the *gelatinization temperature range* (see Table 2). Gelatinization usually occurs over a small temperature range with larger starch granules generally gelatinizing first

and smaller granules later. During gelatinization, granules swell extensively (Fig. 5). Thus, a 1 % starch slurry in cold water has low viscosity, but on heating a thick paste is produced wherein almost all the water has entered the granules and combined with them. This causes the granules to press tightly against each other. The viscosity of the paste results from resistance to the flow of the swollen granules that now occupy nearly the entire volume. Highly swollen granules are fragile and disintegrate on mild stirring. This causes a significant decrease in paste viscosity.

Figure 5. Representation of starch gelatinization process

The swelling and gelatinization of wheat, barley, and maize starch granules have been studied with respect to the effect of amylose, amylopectin, and lipid content [16]. A similar investigation has been performed with rice starch [17]. In the case of wheat, barley, and maize starch it was concluded that granular swelling during gelatinization was mainly a function of amylopectin content. Gelatinization has been studied by scanning electron microscopy and a honeycomb-like structure has been noted on gelatinization [18]. Visual characteristics of starch pastes have been investigated, concentrating specifically on clarity and whiteness [19]. Potato starch paste exhibited the greatest clarity, wheat and corn were intermediate in clarity, and high amylose corn paste was of very low clarity.

Starch swelling rates are greatly increased at pH 10.0 and above. At low pH, the peak viscosity (see Section 1.4.2) of starch pastes is markedly reduced, along with a rapid loss of viscosity on cooking. This is due to extensive hydrolysis of starch to form nonthickening dextrins (low molecular mass oligosaccharides derived from starch).

1.4.1. X-Ray Patterns

The linear nature of corn [20] and potato [21] amylose was proposed in 1940 and confirmed [22] three years later. However, evidence now exists that some amyloses may contain a few very long branches.

X-ray diffraction has been useful in examining the structure of both intact starch and amylose. Starch naturally occurs in three crystalline modifications designated A (cereal), B (tuber), and C (smooth pea and various beans). Starch which is precipitated from solution, or complexed with organic molecules, adopts the so- called *V structure* (Verkleisterung). Amylose also exists in A, B, C, and V structures. Marchessault and coworkers [23] studied the chain conformation of B-amylose and proposed that *B-amylose* is helical with an integral number of α-D-glucopyranosyl residues per turn. The density of B-amylose suggests a helical structure with six α-D-glucopyranosyl residues per unit cell and 3 – 4 molecules of water of hydration. Sixfold helices are energetically favored and have a hydrogen bond between the C-2 hydroxyl group of one α-D-glucopyranosyl unit and the C-3 hydroxyl group of the succeeding sugar unit. Left-handed helices are slightly favored over right-handed ones. It was thus concluded that solid-state B-amylose exists as a left-handed sixfold helix. Amylose triacetate, which exists in a left-handed helix, forms B-amylose upon saponification [24]. Calculations show that *V-amylose,* having a fiber repeat of about 80 pm, is more stable as a left-handed helix than as a right-handed one [25]. The easy conversion of V-amylose to B-amylose [26] implies that no extensive molecular reorganization accompanies the reversal of chain chirality. It seems likely that amylose, in the solid state, exists as a left-handed helical polymer with six α-D-glucopyranosyl units per turn.

A model proposed by Kreger [27] in which amylose exists as a threefold helix has been examined [28]. Although this model is consistent with some of the amylose X-ray data, it has not received wide acceptance. It should be noted that the model of the starch granule of Frey – Wyssling [28] employs radially oriented low-molecular-mass amylose as a threefold helix. This explains the granule's positive birefringence and proposes a higher-molecular-

mass amylose (DP > 280) as a sixfold helix running tangentially to the granule surface.

1.4.2. Rheological Properties

For thickening foods, sizing and coating papers, textile sizing, use in drilling muds, adhesive formulations, and many other applications, starch gelatinization is required. When starch is cooked, flow behavior of the slurry changes significantly as the suspension becomes a mixture of swollen granules, partially disintegrated granules, and molecularly dispersed granule contents (mostly amylose). The cooked product is termed a starch paste and transition from a granular suspension to a cooked paste is accompanied by an increase in apparent viscosity. Although the term viscosity is generally used, starch pastes are non-Newtonian and a better description is that pastes develop resistance to deformation or flow.

On cooling, paste consistency increases because side-by-side molecular associations form junction zones that increase paste resistance to deformation or flow. Therefore, when cooled, pastes may remain fluid or form gels with considerable strength. Starch manufacturers and users both require techniques for judging starch quality and flow behavior in its applications. For these reasons measurements of viscosity, gel rigidity, and gel strength have been devised.

A *Brabender viscoamylograph* provides information on gelatinization as well as on the properties of the cooled paste. This instrument records the torque needed to counteract the viscosity that develops when a starch suspension is subjected to heating and cooling regimes. The temperature at which the first significant rise in viscosity occurs depends on starch concentration. It is usually higher than the gelatinization temperature that is determined by loss of birefringence. Viscosity is measured in arbitrary units (Brabender units) that reflect paste consistency; for this reason, Brabender results are described in terms of paste properties and pasting temperatures at specific times. The Amylograph Handbook describes the theory, construction, applications, sources of error, troubleshooting, and adjustment of Brabender units [29].

A typical Brabender curve is shown in Figure 6. Six important points on the Brabender curve are generally recognized:

1) *Pasting Temperature.* Indicates onset of paste formation; varies with starch type or modification and with additives in the starch slurry.
2) *Peak Viscosity.* Cited regardless of the temperature at which the peak is attained.
3) *Viscosity at 95* °C. Related to ease of cooking the starch.
4) *Viscosity after 1 h at 95 °C.* Shows cooked paste stability, or lack of stability under relatively low shear.
5) *Viscosity at 50* °C. Measures the setback (increase in viscosity) that occurs when the hot paste is cooled.
6) *Viscosity after 30 min at 50* °C. Related to stability of cooked paste under simulated use conditions.

Figure 6. Representative Brabender amylograph curve
For explanation of points 1 – 6 text

Other chemicals in the starch dispersion may have a significant effect on gelatinization and gelation. This is especially true in the use of starch in foods. High *sugar* concentrations lower the rate of starch gelatinization, the peak viscosity, and the gel strength. Disaccharides are more effective in delaying gelatinization and reducing peak viscosity than monosaccharides [30]. Sugars may decrease gel strength by exerting a plasticizing action and interfering with formation of starch junction zones. *Lipids,* such as the triacylglycerol fats and oils, and lipid-related materials, such as mono- and diglycerides may also affect starch gelatinization (Section 1.4.4). Wheat starch contains up to 1 % lipids consisting

mainly of lysophosphatidylcholines of palmitic and linoleic acids which are principally complexed with amylose. Such complexes retard starch hydration and lower peak viscosity on gelatinization. These complexes also are more slowly hydrolyzed by starch amylases.

Because of the essentially neutral character of starch, low concentrations of *salts* have little effect on gelatinization and gelation. Exceptions include potato amylopectin, which contains some phosphate groups, and manufactured ionic starches. With these starches salts may either increase or decrease swelling, depending on conditions [30].

Starch-thickened *acidic* foods (pie fillings, salad dressings) usually have pH values in the range 4 – 7 which has little effect on starch gelatinization. At lower pH values starch hydrolysis occurs, yielding nonthickening dextrins (starch breakdown to oligosaccharides). To avoid thinning in acidic starch-thickened foods, a *cross-linked starch* (see Section 2.2.3) may be selected. Since cross-linked molecules are quite large, extensive hydrolysis is required to decrease viscosity significantly.

1.4.3. Water Activity

In foods and other systems, water is not just a medium for reaction, but is also an active ingredient used to control reactions, texture, and general physical and biological behavior. However, total water content is not the important factor, but rather the availability of water (water activity, a_w). Water activity may be defined as the ratio of water vapor pressure over a sample p to the water vapor pressure over pure water p_0 under the same conditions

$$a_w = \frac{p}{p_0}$$

Alternatively, it may be expressed as the equilibrium relative humidity *ERH* of the atmosphere surrounding a sample divided by 100

$$a_w = \frac{ERH}{100}$$

Water activity is affected by strong water-binding agents or hydrophilic parts of other molecules. If water-binding agents are present in starch preparations, water activity is lower and gelatinization is inhibited to varying extents. Strong water-binding constituents retard starch gelatinization by binding and holding the water needed for gelatinization.

1.4.4. Amylose Complexes

Helical amylose molecules can entrap other organic molecules, such as fatty acids as well as inorganic molecules such as iodine. Such complexes are called inclusion compounds and the amount of iodine binding is a measure of amylose content. Amylose can be separated from amylopectin by addition of *n*-butanol to a hot dispersion and allowing the mixture to cool slowly. On cooling, crystals of butanol – amylose separate and can be removed by filtration or centrifugation [31].

Lipids and emulsifiers, such as mono- and diacylglycerol, affect starch gelatinization. Fats that complex with amylose retard granule swelling. Fat, in the absence of emulsifiers, decreases the temperature at which maximum viscosity occurs but does not affect the maximum viscosity. Corn starch normally gelatinizes to produce a maximum viscosity at 92 °C, but in the presence of 9 – 12 % fat, maximum viscosity occurs at 82 °C.

Monoacylglycerols with acyl chain length of 16 – 18 carbon atoms increase the gelatinization temperature. They also decrease the temperature of maximum viscosity, the temperature of gel formation, and the gel strength. Fatty acids or the fatty acid chains of monoacylglycerols form inclusion complexes with amylose, and possibly with longer outer chains of amylopectin (see Fig. 7). Such complexes are not easily leached from the granule and inhibit entry of water into the starch granule. The lipid – amylose complex also limits retrogradation by interfering with the formation of junction zones between starch molecules.

Figure 7. Complexation of a fatty acid-like chain with helical amylose segment (a = helical amylose; b = fatty acid chain)

1.5. Composition of Native Starches

Normal starches contain about 25 % linear amylose (Table 3). Particular varieties of corn, called *high-amylose corn*, produce starches with amylose contents up to 85 %, although most commercial varieties contain ca. 65 % amylose. High-amylose starches are difficult to gelatinize, often requiring temperatures in excess of 100 °C at > 1 bar. At the other extreme, some starches consist only of branched *amylopectin* (Table 3). These include waxy corn, waxy barley, and waxy or glutinous rice. They produce clear cooked pastes, resembling those of root or tuber starches. These starch pastes are fairly stable to retrogradation due to their lack of amylose.

The term *retrogradation* denotes spontaneous changes during the aging of starch solutions, pastes, or gels that lead to an increase in the degree of order. Retrogradation is crystallization due to the formation of hydrogen bonds between hydroxyl groups of neighboring starch molecules. Retrogradation kinetics of numerous starches have been studied by differential scanning calorimetry and rheology [32, 33]. Potato and pea starches are prone to retrogradation while waxy rice and modified waxy corn are least susceptible.

1.6. Industrial Starch Production Processes

1.6.1. Corn and Sorghum Starch

Corn (maize, *Zea mays* L.) has been grown for 5000 – 7000 years and was probably initially cultivated in Central Mexico. Early corn was quite different from modern varieties, which were derived by both random and scientific selection. Corn types available include popcorn, sweet corn, dent corn, flint corn, and flour corn. Corn's availability at low prices, its storability, and 70 % starch content has greatly expanded its use in commercial production of starch.

Grain sorghum (*Sorghum bicolor* M.), was probably initially cultivated 5000 – 7000 years ago in Eastern Africa. Although sorghum resembles corn in chemical composition, it is generally considered to be inferior for food, feed, and industrial uses. Sorghum can be cultivated effectively in semi-arid regions and is milled similarly to corn.

A single kernel of corn is a caryopsis (a berry) borne on an ear. This berry matures about 60 days after pollination and corn is typically harvested in late summer or early fall. In sorghum, the seeds are borne on a terminal, bisexual head, or rachis.

Corn (and sorghum) wet milling consists of several major steps (Fig. 8): (1) cleaning the grain; (2) steeping; (3) milling and fraction separation; (4) starch processing; and (5) starch drying.

Figure 8. Flow sheet for corn (sorghum) starch production

Cleaning. Grain is first cleaned by screening and by magnetic means to remove foreign material including metal.

Steeping. The grain is steeped to soften the kernel and facilitate its separation into components. This process involves steeping in countercurrent water containing 0.10 % sulfur dioxide at 48 – 52 °C for 30 – 40 h. Sulfur dioxide combats growth of spoilage organisms and maximizes the starch yield. Sulfur dioxide also reacts with the protein matrix to disperse the glutelin by breaking disulfide bonds and releasing extra starch. Proper steeping temperature

Table 3. Comparison of composition and properties of some commercial starches

	Starch content, wt %	H_2O content, wt %	Protein content, wt %	pH	Amylose content, wt %	Amylopectin content, wt %	Specific gravity

Waxy		12	0.13		0	100	1.5

is critical to promote the growth of lactic acid bacteria. Growth of these bacteria lowers the steep pH, restricting the growth of other organisms. Steep water pH is typically ca. 4.0, and is highly buffered. Steep water is concentrated, dried by absorption on corn fiber, and sold as cattle food. Alternatively, it is further processed to remove phytic acid or sold as nutrient for commercial fermentation to produce, for example, antibiotics.

Milling and Fraction Separation. After steeping, grain is milled to obtain separation of components. Steeped grain is first put through an *attrition mill* (Bauer type) to release the oil- containing germ which is removed by centrifugation in hydrocyclones. Next, the residual grain is *ground* between stones to release starch granules from their containment in proteinaceous cells. The slurry is *screened* to separate the corn hull or seed coat which is recovered as a fibrous mass. The remaining starch slurry is more strongly centrifuged to separate starch granules that are washed free of protein and salts and are dried in continuous driers. The isolated germ is partially dried prior to hexane extraction or mechanical removal of corn oil.

Centrifugation. Usually the removal of starch is performed in centrifuges or hydrocyclone batteries that can separate not only the starch but also the insoluble gluten fraction of protein.

Gluten is less dense (1.1 g/cm^3) than starch (1.5 g/cm^3) and is thus easily separated by centrifugal forces. Starch thus produced contains 1 – 2 % protein, which may be removed by a second starch washing with water and centrifugation to give a starch with a final protein content of < 0.38 %. In the case of *sorghum*, starch and gluten are more difficult to separate because the sorghum pericarp is fragile compared to corn. Separation is improved if the kernels are dehulled before milling. This produces a cleaner separation of starch from gluten, giving a starch of low color and protein content.

The final starch slurry can be dried and sold as unmodified starch, or the starch can be modified (see later sections) and dried, or gelatinized and dried. It also can be acid or enzyme hydrolyzed to a syrup which may be used directly or fermented to produce ethanol [*64-17-5*] or other chemical feedstocks.

Drying. Starch is usually dried by flash drying. In this method starch slurry is centrifuged or filtered and the moist starch is introduced at the bottom of a stream of rapidly moving hot air (93 – 127 °C). Drying is rapid and the starch is collected in cyclones. Drying parameters can be used to control both bulk density and particle size. Evaporation of the water requires so much energy that the wet-milling industry is the second most energy intensive food industry.

1.6.2. Wheat Starch

Wheat has been utilized by humans for 8000 – 9000 years. Its cultivation probably began in what is now Iraq. The first instance of commercial manufacture of wheat starch was in England in the 1500s. Wheat is mainly used in human food, while on the contrary much of the corn

grown is used in animal feed, and the world annually produces more wheat than corn. Wheat is harvested by mechanical means and wheat starch is separated by one of several processing methods such as the Martin, Batter, Fesca, ammonia, or the acid process, by wet wheat milling, whole wheat fractionation, the Rasio, or the hydrocyclone process. The first two processes are most common.

Martin Process. The Martin (dough ball) process, invented in 1835, uses wheat flour as its raw material (Fig. 9). Wheat flour and water (2 : 1) are blended and the dough is allowed to rest, hydrate, and strengthen the gluten matrix. The dough is then kneaded while washing with water to remove the starch. The residual gluten is partially dried by roller compression and then flash dried. Starch slurry from the dough washer is screened to remove any remaining gluten and then fine screened to remove bran. The starch slurry is centrifuged to produce a high solids starch cake which is flash dried. Starch is dried to 10 – 12 % moisture and contains ca. 0.3 % protein.

Figure 9. Flow sheet of the Martin process

Batter Process. The Batter process is derived from the Martin process but differs in the way the dough is formed and the way it is subsequently treated (Fig. 10). Wheat flour and water (ca. a 1 : 1 ratio) are mixed and the produced dough is allowed to rest for 30 min. The dough is then vigorously mixed with twice its weight of water. Gluten is separated from this mixture by screening and bran is removed from the starch by additional screenings. Centrifugal separation of the starch slurry separates the large starch granules (*type A starch*) from the small granules, damaged granules, and pentosan complexes (*type B starch*). Type A starch is essentially pure and may be dewatered and flash dried. Type B starch is processed again in a similar way but is of lower purity. Large wheat starch granules are extensively used in making carbonless copy paper where the granules serve as agents to prevent premature bursting of the ink microcapsules.

Figure 10. Flow sheet of the Batter process

1.6.3. Potato Starch

Potato starch is produced in large quantities in Europe, especially in the Netherlands, Poland, and Germany. Potato starch is usually isolated

from cull potatoes, surplus potatoes, or waste streams from potato processing plants (Fig. 11).

Figure 11. Flow sheet for potato starch production

Cull or surplus potatoes are washed with water to remove dirt and other foreign matter. They are then disintegrated by a saw blade rasp or hammermill and the mashed product is screened to remove peels and fiber. During this process water containing sulfur dioxide is used to preserve color and inhibit enzymatic browning. Screening separates starch from pulp. The pulp can be reground and a second extraction performed to obtain a total starch yield of 12 – 19 %, based on raw potatoes.

Starch isolated as described above is reslurried to remove water solubles and then partially dried in a continuous centrifuge. This is followed by another washing and centrifugation to obtain a purified slurry of potato starch. The slurry obtained from these operations is filtered and flash dried (< 175 °C inlet temperature). The potato starch, dried to 17 – 18 % moisture, is subsequently screened and packaged.

1.6.4. Rice Starch

Rice (*Oryza sativa* L.) cultivation probably originated in Asia where the crop is still very important. Rice is an important commercial crop in India, China, the United States, and Italy. In the United States more than 90 % of the rice crop is produced in Arkansas, Louisiana, Texas, and California. Rice grain consists of a hull surrounding an edible berry, or caryopsis. The outer fibrous layers of the caryopsis conceal a starchy endosperm and the germ. The endosperm consists principally of starch granules and protein. Little matrix protein is evident in rice endosperm.

Broken rice is reacted with 0.3 – 0.5 % sodium hydroxide solution to soften the grain and assist in protein removal. The alkali treated grain is hammermilled and the broken cell walls are removed by screening. The rice starch slurry is purified by centrifugation and dried.

1.6.5. Tapioca Starch

Tapioca starch is produced by processing the tuberous roots of the tapioca plant, also called cassava, manioc, or yuca (*Manihot esculenta*), a native of many equatorial regions. Cassava roots may be "sweet" (containing $\leq$50 mg of HCN per kilogram fresh root) or "bitter" (containing $\geq$250 mg of HCN per kilogram fresh root). Sweet root varieties are grown for food starch production while bitter varieties are used for other industrial purposes. In both cases, hydrogen cyanide content is eliminated or reduced during processing.

Root harvesting is usually manual and yields vary from 11 200 – 44 800 kg/ha. Typical root composition is 70 % water, 24 % starch, 2 % fiber, 1 % protein, and 3 % fats, minerals, and sugars. Tubers need to be processed within 48 h of harvest. They are first washed to remove dirt and then the outer skin is removed. The root is chopped into small pieces and passed through a rasp disintegrator. In this process hydrogen cyanide is released by natural enzymes and removed by washing.

Cassava root pulp is washed on screens. The starch passes through but the fibers are retained. The fiber fraction is used in fertilizer or cattle feed. After screening the starch slurry is centrifuged to separate the starch from fiber fines and other soluble material. Starch collected in this manner can be reslurried and recentrifuged to obtain greater purity. Sulfur dioxide (0.05 %)

is usually added to process water to inhibit microbial growth. Slurried starch from the purification process is dewatered by centrifugation or filtration followed by drying on a drum, belt, or tunnel, or by flash drying. Flash drying is most common. Tapioca starch is mainly used unmodified but can be modified as is done with corn starch. The viscosity of tapioca starch dispersions is a function of plant variety, geographical conditions, harvest time, root age, soil fertility, rainfall, and manufacturing practices during starch production.

1.6.6. Arrowroot Starch

Arrowroot starch comes from the root of the tropical perennial *Maranta arundinacea.* Roots are harvested after 6 – 12 months growth and contain 20 % or more starch, extracted as described for tapioca starch. The outer skin of arrowroot root must be completely removed to prevent off- color and off-taste in the starch. Arrowroot starch is mainly a product of China, Brazil, and St. Vincent in the West Indies.

1.6.7. Sago Starch

Sago starch is a granulated product which has been originally obtained from stems of several species of palms, principally *Metroxylon, Arenga,* and *Mauritia sp.* Trees of eight or more years old are used. Principal production occurs in Sarawak and New Guinea. Cut palm trunks are split and the pith removed and kneaded in water to release the starch which is screened to remove fiber, filtered, and dried. A single palm trunk can yield 100 – 200 kg sago starch. Sago starch granules are 20 – 60 µm in diameter.

Nowadays sago is also produced from tuberous roots of other tropical plants, such as cassava. Some comparative properties of commercial starches are given in Table 3.

1.7. Uses

Uses in Foods. Underivatized (native) starch is widely used in foods, both as an isolated, pure product and as a constituent of cereal grains, where it thickens and forms gels. It performs this function by undergoing gelatinization (see Section 1.4). In principle, the function of starch is to act as a "water sink", absorbing much of the available free water and providing desirable structure and texture in many foods. Starch may also be cooked and dried to provide a cold water dispersible, pregelatinized product which is the basis of many instant gel and pudding products.

Pea starches have been proposed for use in preparation of gels requiring ca. 50 % less starch than comparable corn starch gels, in production of extruded products, in production of pulpy products via freeze – thaw technology, and in production of instant starches with cold water swelling and gelling properties [34].

The viscoelastic behavior of starch gels as a function of time has been reported [35].

Starch may be hydrolyzed and/or isomerized to produce corn syrup sweeteners, corn syrup solids, or high fructose corn syrup (HFCS) (→ Glucose and Glucose-Containing Syrups). Alternatively, it may be fermented to produce ethanol and other industrial chemicals (→ Ethanol).

Other Uses. Unmodified starch also finds applications as textile sizings and adhesives, and is useful as a wet-end adhesive in the paper industry. It is used in oil field applications (in its pregelatinized form) where it functions as a suspending agent and maintains drilling fluid viscosity and decreases fluid loss.

In the pharmaceutical industry starch is used as a tablet binder, and in cosmetics rice starch in particular is employed as a dusting powder.

2. Modified Starches

Starch may be modified in numerous ways, both physically and chemically. These modifications are discussed in the following sections. Some properties of various corn starch derivatives are shown in Table 4.

2.1. Physically Modified Starches

Pregelatinized starch is a common ingredient in foods as well as other industrial applications. It is commercially prepared by putting a starch slurry in a trough between two counterrotating rolls internally heated by steam. The starch slurry is

heated above the gelatinization temperature and is then drawn downward between the nip of the hot rolls to form a thin film. The film dries as the rolls turn and is scraped off and ground to produce a fine powder. Pregelatinized starch can also be prepared by spray drying a gelatinized starch paste. Pregelatinized starch quickly rehydrates in cold water. In foods it can be uniformly incorporated without heating to provide thickening, binding, and other properties. Pregelatinized starch is an essential component in foods in which cooking is not employed, such as in instant puddings, pie fillings, and cake frostings.

Table 4. Properties of various corn starch derivatives

Type	Gelatinization temperature range, °C	Distinguishing properties
Normal	62 – 72	poor freeze – thaw stability
Waxy	63 – 72	little retrogradation
High-amylose	66 – 92	granules less birefringent than those of normal starches
Acid-modified	69 – 79	decreased hot-paste viscosity compared to unmodified starches
Cross-linked	higher than unmodified, dependent on degree of cross-linking	reduced peak viscosity, increased paste stability
Acetylated	55 – 65	excellent paste clarity and stability, good freeze – thaw stability
Phosphate, monoesters	56 – 66	reduced gelatinization temperature, reduced retrogradation
Hydroxypropyl	58 – 68 (DS 0.04)*	increased paste clarity, reduced retrogradation, good freeze – thaw stability

* DS = degree of substitution.

Pregelatinized starches have been incorporated into extruded oat-based snack foods where they provide well expanded, crisp products and lead to reduced product rancidity. Incorporation of starch in these foods also reduces wear and tear on the cooker extruder [36].

Pregelatinization of starch typically increases ease of digestibility, although not necessarily in a linear fashion [37]. Although pregelatinized starches are rapidly digested, they do not differ in their calorific value from other starches except for the case of high-amylose starch, which is so difficult to solubilize that any ungelatinized granules may be unavailable for digestion. Some precooked starches give low food value to some animals because the high viscosity produced on eating may induce satiety so that the animal eats less [38, 39].

2.2. Chemically Modified Starches

Starch molecules, both in free and granular form, are subject to chemical modification. Thus, starch is modified in various ways to produce acid-modified (thin-boiling), oxidized, cross-linked (e.g., by formation of distarch phosphates or adipates), partially esterified (either as carboxylate esters or phosphate esters), or partially etherified starch, or converted to cationic derivatives. These modifications, normally present at very low concentrations in starch preparations, produce dramatic differences in the physical and chemical properties of starch and lead to a multitude of uses in both food and nonfood applications.

2.2.1. Acid-Modified Starch

Treatment of starches such as dent corn starch with acid at a temperature below the gelatinization temperature produces virtually no change in granular appearance [40], and only a small change is noted in granular birefringence patterns [41, 42]. However, changes are produced that affect the gelation of acid-modified starch such as a lower hot paste viscosity [43 – 50], lower intrinsic viscosity [51], lower iodine affinity [51], and an increased solubility in water at temperatures just above the gelatinization temperature [45, 52, 53].

Acid treatments of gelatinized starch date back to 1811, when Kirchoff produced D-glucose [*50-99-7*] from starch by acid hydrolysis. Treatment of ungelatinized starch was reported by Naegeli in 1874 [54] who found that such treatments dissolved much of the starch granule and left a residue of short starch molecules (DP ca. 25) (Naegeli dextrins). Commercial production of acid-modified starch dates to between 1897 and 1901 [55, 56].

Acid-modified, or thin-boiling starch has a lower molecular mass, or degree of polymerization than native starch [57, 58]. For example, the DP of potato starch, which is initially 1630, drops to 990 after 4 h treatment with 0.2 N HCl at 45 °C.

Acid-modified starch is prepared today by heating a starch slurry with 36 – 40 % solids content to 40 – 60 °C (below the gelatinization

temperature of the starch) with hydrochloric acid for one to several hours. When the desired degree of hydrolysis is achieved, as judged by the viscosity of the cooked modified starch, the acid is neutralized, and the granular modified starch is filtered, washed, and dried. Sometimes other acids are used such as sulfuric acid, with different reaction conditions.

The change in iodine binding capacity (see Section 1.4.4) or iodine affinity (which reflects the amount of amylose or linear starch material) after acid treatment varies with the type of starch. With corn starch only a little change in iodine affinity occurs for moderate acid conversions (relative product fluidity in the range 40; fluidity = 1/viscosity). This result is taken as an indication of preferential acid attack on the amylopectin component of the starch.

As the molecular size of starch decreases due to acid hydrolysis, the number of reducing end groups increases. This is measured commercially by the alkali number which increases as the extent of hydrolysis increases (there is an increase in fluidity) [59] (see Table 5). As acid hydrolysis proceeds, starch solubility in hot water increases [53].

Table 5. Relation of fluidity of starch dispersions to alkali number [59]

Relative fluidity	Alkali number*
20	14.5
40	15
90	41.5

* Alkali number = milliequivalents of alkali consumed per 10 g of calculated dry starch during a standard 1 h digestion in 0.1 M sodium hydroxide at 100 °C.

Acid treatment causes hydrolysis of glycosidic bonds in the starch molecules

For *dispersed starch* the (1,4)-α-D linkages are more susceptible to acid cleavage than the (1,6)-α-D branch points [60]. However, in *granular starch*, portions containing many of the (1,4)-α-D linkages (amylose, long outer chains of amylopectin) are present in the crystalline regions of the granule. Hence, the (1,6)-α-D linkages become more accessible and susceptible to acid hydrolysis. For hydrolysis of potato starch, moisture conditioning without swelling may facilitate hydrolysis [58]. This, with other data, suggests that acid conversion occurs in two steps:

1) An initial attack on the amorphous regions, rich in amylopectin, especially the vulnerable (1,6)-α-D branch points
2) A slower attack on the more highly organized and crystalline regions of amylose and amylopectin

Uses. Acid-modified starches are employed in *textile manufacture* where they function as warp sizes [61, 62] to increase yarn strength and abrasion resistance during weaving. These uses have somewhat declined due to increased use of poly(vinyl alcohol). Starches with different fluidities are used for specific types of yarns. Thus, low fluidity starch is used for heavy yarns and high fluidity starch is used for light yarns. Starch concentrations of 10 – 12 % are usual for such sizing applications.

Acid-modified starch is also used in the manufacture of *gypsum board* for dry wall construction where it serves to bond plaster and paper together.

Acid-modified starches find use in *starch gum confectionery*, an example being candy orange slices. To produce proper texture, the acid-modified starch is boiled together with sugar, corn syrup, and water to form highly concentrated pastes which form very firm gels on cooling. Not surprisingly, the granule structure is almost completely disintegrated in the cooking process. The composition of a typical starch gum confectionery is given below (for the definition of the term dextrose equivalent, see → Glucose and Glucose-Containing Syrups, Chap. 4):

Sucrose	45.4 kg
Corn syrup (dextrose equivalent 63)	68.1 kg
Acid-modified starch (fluidity 70)	31.8 kg
Water	26.5 L

Production of such confectioneries begins with heating of corn syrup, water, and acid-modified starch to just below boiling in a steam kettle. When the starch has been dispersed, sugar is added and the mixture is heated to 103 °C and the heat removed. The water content of the cooked paste is adjusted to 22 – 23 % and the mixture is put through an injection cooker at 140 °C. Flavor and color are added and the paste poured into molds and allowed to set to a firm gel. As a final step, the molded gel is coated with sucrose using a sugar sander.

Thin-boiling starch is also applied in *paper manufacture* as a paper size where it increases the strength of Kraft linerboard and improves bleached board printability. It is typically applied at 66 – 71 °C and pH 7.5 – 8.0. A high solid, acid-modified carrier starch is used to increase the production rate of corrugated board [63].

2.2.2. Oxidized Starch

Oxidation of starch has a long history beginning with Liebig [64] who used chlorine to oxidize starch in 1829. Somewhat later Lieben and Reichardt [65] used bromine. These oxidations by halogens, and the hypohalites produced by their reaction with water, may proceed in four different ways, producing distinct products.

1) *Oxidation of reducing end aldehyde to carboxyl groups*, producing aldonic acid end units; namely, D-gluconic acid end units.

2) *Oxidation of the C-6 Methylol Group to a Carboxyl Group*. D-Glucuronic acid was isolated and identified from starch oxidized by bromine [66]. The oxidation probably proceeds by way of the 6-aldehyde derivative.

3) *Oxidation of Starch Secondary Hydroxyl to Ketone Groups.* This reaction is shown below for oxidation of the 3-OH to a carbonyl group. Bromine oxidation of starch [67] resulted in a product from which an oxime could be prepared, thus indicating the presence of ketone groups.

4) *Oxidation of 2,3-Glycol Units to Dialdehyde and Dicarboxylic Acid Units* (*Glycol Cleavage*). Evidence for this reaction was first obtained by Farley and Hixon [66]. Oxidative attack varies with the location of hydroxyl groups and with the nature of the oxidant. Oxidation at C-1, C-2, C-3, and C-6 determines the properties of the resulting starch product.

Common sodium hypochlorite-oxidized starch is granular in form with few surface changes noted by scanning electron microscopy. It retains its birefringence and granular appearance [68]; it is whiter because of the bleaching action of sodium hypochlorite. Oxidation occurs mainly in the amorphous regions of the granule. Oxidized starch is less stable to heat than native starch, tending to turn yellow or brown upon heating due to further reaction of carboxyl or aldehyde groups produced by the oxidation [69].

Heated aqueous dispersions of oxidized starches have lower intrinsic viscosities which depend on the extent of oxidation [68] and have a lower gelatinization temperature range than native starches [70, 71]. The aqueous dispersions have greater clarity than those of unmodified starch and exhibit a lower tendency to gel or setback [72].

Production. Commercially a controlled amount of chlorine gas is bubbled into dilute aqueous alkali to produce hypochlorite ions. The amounts of available sodium hydroxide and chlorine determine which of the four types of oxidation will principally occur. Reaction is performed on a rigorously stirred starch slurry of about 33 – 44 % solids content. The pH of the slurry is adjusted to 8 – 10 with sodium hydroxide and chlorine added to produce hypochlorite with 5 – 10 % available chlorine. Temperature is maintained at 21 – 38 °C by controlling the rate of hypochlorite addition or by external cooling. When the desired degree of oxidation is obtained (usually determined by viscosity analysis) the pH is decreased to 5 – 7 and excess chlorine is destroyed by reaction with reducing agents such as sodium bisulfite or sulfur dioxide. The modified starch is isolated by centrifugation or filtration and is washed and dried.

Uses. Oxidation introduces an increasing number of carbonyl and carboxyl groups into the starch molecules, which in turn cause changes in the chemical and physical properties [73, 74]. Most commercial oxidized starches contain about 1.1 % carboxyl groups. These groups play a predominant role in determining the properties of the starch derivative which is used mostly in the *paper industry*. 80 – 85 % of oxidized starch is used in paper production where it acts as a coating binder for high-solid pigment coating colors. In this application, pigment compatibility is important and the starch should not affect the rheology or the water binding characteristics of the coating color [70, 75].

Oxidized starch is used also as a surface size in paper and paperboard manufacture. Here it seals pores, improves surface strength, and provides ink holdout. As a wet-end additive in paper manufacture, oxidized starch reduces pigment retention by acting as a pigment dispersant [76].

Oxidized starches have a long history of use in *textile manufacture* where they function primarily as warp sizes but also in finishing and printing. As warp sizes they provide abrasion resistance for yarn but are now being replaced by synthetic polymers.

Oxidized starch has been used in *laundry finishing* and in making *construction materials* such as wallboard and ceiling tiles. In these applications, starch provides sizing and adhesive characteristics.

Lightly oxidized starches have application in *breading batters* for deep fried foods where they give good adhesion of the breading to the food [77].

Periodate oxidized starch is a good substitute for formaldehyde or glutaraldehyde as *hardening agents* in gelatin-immobilization of yeast cells [78].

2.2.3. Cross-Linked Starch

Cross-linking of starch reinforces the intermolecular binding by introducing covalent bonds to supplement natural intermolecular hydrogen bonds. Cross-linking restricts granule swelling, decreases peak viscosity on cooking, and increases the stability of the gelatinized granule. Most cross-linked starches are quite lightly derivatized, containing ca. one cross-link for every 100 to 3000 anhydro-D-glucosyl units (degree of substitution, DS 0.01 – 0.003).

Cross-linked starch granules also appear unchanged by microscopic investigation but they are more resistant to swelling than unmodified starch. This is especially evident when their dispersions are placed in a Brabender viscoamylograph or similar instrument. Cooked cross-linked starch granules are less fragile than native starch granules and more resistant to high shear, elevated temperatures, or low pH [79]. At low degree of substitution an increase in peak viscosity is observed when measured by a Brabender amylograph but with high DS no viscosity peak occurs when aqueous dispersions are gelatinized. Loss of peak viscosity is caused by constrained swelling of the granule due to extensive cross-linking of the starch molecules. If the degree of cross-linking is sufficient, gelatinization will not take place at 100 °C or even in an autoclave. Cross-linked starches of low DS (< 1) have improved textures; they are less rubbery and stringy than pastes and gels made from unmodified native starches. Cross-linking is sometimes performed in combination with oxidation [80] , phosphorylation [81], hydroxyalkylation [81], or esterification [82].

Production. Cross-linking reactions are usually performed on starch slurries which are

then reacted with specific bi- or polyfunctional reagents such as phosphorus oxychloride, sodium trimetaphosphate, epichlorohydrin, or mixed anhydrides such as those of acetic and adipic acid. Slurry reaction temperatures may range from 25 to 50 °C. After cross-linking is complete, the cross-linked starch is isolated by filtration, washed to remove excess reagents and salts, and dried.

The reaction of starch with *phosphorus oxychloride* to produce a distarch phosphate is shown below:

Typically, the reaction is carried out at pH 8 to 12 and with 0.005 to 0.25 % phosphorus oxychloride. Frequently, sodium chloride or sodium sulfate is added to the slurry to inhibit granule swelling and starch leaching from the granule [83]. When the concentration of phosphorus oxychloride is increased from 0.005 – 0.25 % to 1 % or more, the resulting starch phosphates are highly cross-linked.

Epichlorohydrin is commonly used [80] to cross-link starch under alkaline conditions, as shown below:

Common *mixed anhydride* cross-linking agents are those of acetic and dicarboxylic acids, such as adipic acid [82]. Other reagents used to cross-link starch include (but are not limited to) vinyl sulfone, diepoxides, cyanuric chloride, toluene-2,4-diisocyanate, *N,N*-bismethylene-bisacrylamide, phosgene, imidazolides of polybasic carboxylic acids, and aldehydes such as formaldehyde, acetaldehyde, or acrolein [84].

Properties. Cross-linked starches are less soluble in hot water than native starches even though the degree of molecular cross-linking is very low [85]. Material extractable by dimethyl sulfoxide (DMSO) is also reduced by cross-linking (see Table 6) [52].

Table 6. Solubility of waxy and cross-linked waxy sorghum starch in dimethyl sulfoxide at 25 °C [107]

Starch	Time, h	Solubility, %
Waxy	20	100
Cross-linked waxy	45	20

Cross-linking of starch at low degrees has little effect on in vitro digestibility. The calorific value of the cross-linked derivative is the same as that of the unmodified, native starch [86].

Cross-linked starch provides a stable, high viscosity paste that may be subject to high temperature, high shear, or low pH.

Uses. Cross-linked starches with a low DS are extensively used in *foods*. In extrusion cooking, high degrees of cross-linking are necessary to prevent complete granular disintegration. When a short, salve-like consistency is desired, cross-linked waxy corn, potato, or tapioca starch, which is usually also phosphorylated, acetylated, or hydroxypropylated, is used. Cross-linked starch provides texture in salad dressings due to its stability to both low pH and the high shear experienced during homogenization. These derivatized starches are also used in batter mixes for deep-fried foods, fruit pie fillings, puddings, cream style corn, soups, gravies, sauces, and baby foods [79, 87, 88]. In some food systems the starch imparts a desirable pulpy texture [89].

Cross-linked waxy starches are constituents of cake mixes where they improve cake volume, crumb texture, and increase shelf-life, due to decreased rate of becoming stale [90]. Acid-converted cross-linked starches are dispersible in cold water and form gels [91], they are thus used in instant puddings.

Cross-linked starches are used also in antiperspirants [92] and textile printing pastes where

they produce high viscosity and a short, cohesive texture [93]. They have been employed in oil-well drilling muds, printing inks, charcoal briquette binders, fiberglass sizing [94], and textile sizing [95].

2.2.4. Starch Esters

Carboxylate Esters. Starch acetates [*9045-28-7*] have been known for more than 100 years [96]. Those of high DS are soluble in organic solvents with a low polarity but because of the branched amylopectin molecules they are not economically competitive with similar cellulose derivatives. Material with a lower degree of substitution (0.3 – 1.0) is water soluble, whereas most commercial products are even more lightly substituted (DS 0.01 – 0.2). In anhydrous media, the acetylation reaction is very sluggish and, in addition, the granules require prior swelling to allow penetration by the acetylation reagents. Starch acetates can be produced in many ways. Commercial processes typically employ acetic anhydride, with or without catalysts.

Reaction with Acetic Anhydride Alone. Starch does not react with acetic anhydride at ambient temperature and only slightly at 90–140 °C. Cooking and disruption of starch granules followed by ethanol precipitation increases reactivity but acidic catalysts cause starch degradation [99].

Reaction with Acetic Anhydride [*108-24-7*] *in Pyridine* [84]. Starch granules treated with acetic anhydride alone at 20 °C for 5 months showed no reaction. Pyridine treatment [97] rendered the starch granule reactive [98]:

Reaction with Acetic Anhydride and Glacial Acetic Acid. Reaction requires the addition of an acidic catalyst such as sulfuric acid, *p*-toluenesulfonic acid, perchloric acid, or phosphoric acid. The yield of acetylated (and degraded) starch acetate increases at elevated temperature.

Reaction with Acid Anhydride in Dimethyl Sulfoxide (DMSO) [100]. Starch derivatives of acetic, propanoic, and butanoic anhydrides have been prepared up to a DS of 0.08. Triethylamine serves as a catalyst and acid scavenger.

Reaction with Carboxylic Acids. Starch does not react with aqueous acetic acid but with *glacial acetic acid* at 100 °C for 5 – 13 h [101], to give a product with 3 – 6 % content of acetyl groups. Treatment of starch with *concentrated formic acid* leads to gelatinization and simultaneous esterification [102].

Acetylation with Ketene. This reaction [103] can produce starch with an acetyl content of 2.2 – 9.4 %. The reaction is typically performed in acetic acid, diethyl ether, or acetone with an acid catalyst, the most effective of which are sulfuric acid and *p*-toluenesulfonic acid.

These reactions typically lead to a considerable degree of acetylation in the starch granule. More lightly substituted starches (low DS starch acetates) can be produced, e.g., by reaction of starch with *acetic anhydride* in the presence of a base such as 3 % sodium hydroxide [104]. The reaction is carried out at pH 7 – 11 and alternative bases such as other alkali metal hydroxides, calcium hydroxide, or sodium carbonate can be employed. Low DS starch acetates can be produced by reaction of granular starch with *vinyl acetate* [*108-05-4*] [105]:

This reaction requires basic catalysts, such as alkali metal hydroxides, amines, or sodium carbonate. Acetylation is sometimes combined with hydroxypropylation to produce starches having excellent freeze – thaw stability [106].

Properties. Starch acetates with degrees of substitution of ca. 0.5 have roughly the same solubility as normal starch. Starch esters are readily cleaved by alkali, for example, acetylated granular corn starch of 1.8 % acetyl content can be deacetylated in 4 h at 25 °C at pH 11. At low DS (< 1), microscopic examination shows no difference between the granule of starch ester and the native starch granule. Low DS starch acetates have a lower gelatinization temperature, an increased hot cooked paste viscosity, easier

dispersion on cooking, and a decreased setback or final gel strength.

Higher DS starch acetates, with up to 15 % acetyl content, are soluble in water at 50 – 100 °C [107, 108]. When the acetyl content exceeds 40 %, they are only soluble in organic solvents with lower polarity (aromatic hydrocarbons, ketones, nitroalkanes, etc.). Such highly substituted derivatives are insoluble in water, diethyl ether, aliphatic alcohols, and aliphatic hydrocarbons [108].

Starch acetates with a high degree of substitution (DS 2 – 3) have increased densities, specific rotations, and melting temperatures.

Uses. Low DS starch acetates have major use in *foods* where they provide thickness, body, and texture. Certain food applications require a starch derivative with a bland taste, stability to low pH, stability to high shear and temperature, and freeze – thaw stability. Acetylation and/or cross-linking provide such qualities.

Starches containing *0.5 – 2.5 % acetyl content* (the FDA permits up to 2.5 % acetyl content) provide gels of exceptional brilliance and clarity. Such starch acetates are used in canned, baked, and dry foods such as instant gravies and pie fillings. They are used in baby foods and cream pie filling to provide texture. Products which are frozen and thawed (perhaps several times) before use also benefit from a content of starch acetates. Such products include frozen pies and frozen gravies.

Low DS starch acetates are also used in *nonfood applications* such as warp sizing in textiles to provide good yarn adhesion, tensile strength, and flexibility. Starch acetate is easily removed due to its solubility in water [109]. Starch acetates have also been used as fiberglass forming sizes [110] and in the paper industry as a surface size where it improves printability and gives uniform surface strength, porosity, solvent resistance, and abrasion resistance [109]. Such starch esters have also found use in gummed tape formulations.

High DS starch acetate derivatives have fewer uses but have been employed in thermoplastic molding [111] and in films as plasticizers [112].

Phosphate Esters. Because of their ionic character, cooked pastes of starch phosphate monoesters are "thinned" or decreased in viscosity when salts are added. Paste viscosity is also affected by pH [113].

Starch phosphate esters react with aluminum, titanium, and zirconium salts to form insoluble precipitates [114]. Starch phosphates also react with cationic dyes such as methylene blue [115, 116]. Starch phosphate esters are chemically compatible with gelatin, vegetable gums, poly(vinyl alcohol), and polyacrylates [117, 118].

Introduction of a few *distarch phosphate groups* which cause chain cross-linking greatly increases the acid stability of the phosphorylated starch derivative. In starch monophosphate esters, 28 % of the phosphate ester groups are present at C-2, 9 % are at C-3, and 63 % at C-6 of the corresponding D-glucose units. The pK_1 ranges between 1 and 2, and pK_2 between 6 and 7.

Production. Starch phosphate esters can be prepared by reaction of starch with inorganic phosphates such as sodium tripolyphosphate [*7758-29-4*] [117]. The reagent produces phosphate esters with a DS up to 0.01:

$$\text{Starch}-\text{OH} + \text{Na}_5\text{P}_3\text{O}_{10} \longrightarrow \text{Starch}-\text{O}-\overset{\overset{\displaystyle\text{O}}{\|}}{\underset{\underset{\displaystyle\text{O}^-\text{Na}^+}{|}}{\text{P}}}-\text{O}^-\text{Na}^+ + \text{Na}_3\text{HP}_2\text{O}_7$$

To do so, starch is impregnated with phosphate salts in an aqueous slurry. Starch and phosphate are mixed together for 10 – 30 min, then filtered. Typically 40 – 60 % of the phosphate salt is retained by the starch. The pH is carefully adjusted to 5 – 8.5, if the pH is too high, distarch phosphate cross-links will be formed. The final starch phosphate salt is heated at lower temperature (60 °C) to remove moisture, then heated at 120 – 170 °C to effect phosphorylation. This drying – reaction process can be performed by belt or spray drying [119].

Starch phosphates with a *low degree of substitution* can be produced by extrusion of starch with sodium tripolyphosphate [120]. Maximum degree of substitution (DS = 0.0053) is obtained at 200 °C, tripolyphosphate concentration $\geq$ 1.4 g/100 mL, and pH 8.5. Pastes of these starch phosphates have exceptional clarity.

Properties. Cooked aqueous dispersions of starch phosphates compared to natural starch

have increased gel clarity, increased viscosity, a more cohesive texture, and gels that are stable to retrogradation [117].

Uses. Starch phosphate monoesters find application in paper, textiles, adhesives, as scale inhibitors, in flocculation, and numerous other applications. In the *paper industry,* starch phosphates are used as wet-end additives which improve paper strength and filler retention [121], while in *textiles* these esters act as sizes for polyester – cotton, polyester – rayon, and pure cotton yarns [118]. They are also used as thickeners in textile printing inks because they improve ink penetration into cotton.

In *adhesives,* these esters improve storage stability and promote rapid bond strength. Use of 10 mg/L of starch phosphates prevents or inhibits *scale-forming deposits* [122]. *Coal washery tailings* can be flocculated by starch phosphates, in *food* they function as effective oil-in-water emulsifiers [123] as well as good thickeners and stabilizers for puddings [124].

Starch phosphates have also been used in *medicinal films* for the treatment of skin wounds and burns [125]. The film promotes rapid healing and reduces incidence of infection.

2.2.5. Starch Ethers

The two major types of commercially important starch ethers are hydroxyethyl and hydroxypropyl ethers.

Production. The *hydroxyethyl derivatives* are typically produced by reaction of ethylene oxide [*75-21-8*] with starch under alkaline conditions:

A starch slurry of 35 – 45 % solids content is made alkaline with sodium hydroxide, purged with nitrogen gas, and then ethylene oxide is added. Depending on the DS desired, the reaction is conducted for a while at 25 – 50 °C and the hydroxyethylated product is filtered, washed to remove excess reagent and salts, and dried. The mechanism apparently involves abstraction of a hydroxyl proton from a starch molecule by alkali, followed by S_N2 attack of the starchate anion on the highly strained oxirane ring. Commercial hydroxyethyl starch has a DS of about 0.2. Most of the newly formed ether groups (76 – 85 %) are formed at the oxygen bound to C-2, because the order of hydroxyl reactivity is 2-OH > 3-OH ≈ 6-OH [126].

Hydroxypropyl derivatives are prepared in a similar manner as hydroxyethyl derivatives, following the same mechanism with most substitution occurring at 2-OH. To an aqueous starch slurry of 32 – 38 wt %, sodium hydroxide is added to a concentration of 0.5 – 1.0 % (based on the dry weight of the starch). Sodium sulfate (5 – 15 %) is sometimes added to prevent starch swelling. Propylene oxide [*75-56-9*] is added in the amount of 5 – 10 % of the dry weight of starch and the reaction carried out at 52 °C for ca. 24 h. The hydroxypropyl starch is filtered, washed, and dried.

Properties. Hydroxyethyl [*9005-27-0*] and hydroxypropyl [*9049-76-7*] starch are the commercially most important starch ethers. At low degree of substitution the physical properties of these ethers are similar to those of low DS starch acetates. As the DS increases the gelatinization temperature range decreases [127], but rate of granule swelling, clarity of the dispersion [128], and dispersion cohesiveness increases. The tendency to gel or setback is lowered, and solubility in methanol or ethanol is increased [129].

It is possible to prepare films from hydroxypropyl high-amylose corn starch which are water-soluble, transparent, and oxygen impermeable [130]. Hydroxyalkylation results in decreasing digestibility at increasing degree of substitution.

Lightly substituted (low DS) hydroxyethyl or hydroxypropyl starch is similar in properties and appearance to unmodified starch. An increasing DS of either derivative decreases inter-starch hydrogen bonding which lowers pasting temperature and inhibits retrogradation. Hydroxyethyl starch pastes are more stable to added salts including those present in hard water than are the cationic or anionic starches. Hydroxyethyl ether linkages are stable over a wide pH range.

Uses. *Hydroxyethyl starch* is used in the *paper industry* as a surface sizing and coating [109] where it provides strength, stiffness, and ink

holdout. It is also applied in coatings for pigmented paper [131] to achieve good printing quality. Hydroxyethyl starch is also a wet-end additive in papermaking [121] and has been used in many *adhesives* such as bag pastes, case sealing, and label and envelope adhesives because of its excellent water holding and film forming properties [129].

In *textiles,* low DS starch ethers are employed as warp sizing. In *foods,* starch ethers (which are also usually cross-linked) provide thickness and texture and the ability to hold water at low temperature. They are used in milk-based products [132] and salad dressings [133]. The good freeze – thaw stability of the starch ethers permits their use in frozen puddings, sauces, gravies, and fruit pie fillings [134]. Hydroxypropyl, high-amylose starches produce edible, water-soluble food films [135].

2.2.6. Cationic Starch

Cationic starches include tertiary aminoalkyl ethers, quaternary ammonium ethers, aminoethylated starches, cyanamide derivatives, starch anthranilates, and cationic dialdehyde starch (although the last three are commercially less important).

Tertiary Aminoalkyl Derivatives. These derivatives are produced by reaction of the appropriate chloroalkane tertiary amine with starch under alkaline conditions, followed by acidification to produce the desired cationic derivative:

Reactions are conducted at pH 10.5 – 12 and 25 – 50 °C. The mechanism involves the reaction of starch with a nitrogen heterocycle to produce the desired product. Substitution mainly occurs at C-2 [136].

Quaternary Ammonium Starch Derivatives. These derivatives are obtained by reaction of starch with 2,3-epoxypropyltrimethylammonium chloride [137]:

Starch is reacted with this reagent in a 40 – 46 % slurry at pH 11.0 – 12.0. The ratio of alkali to epichlorohydrin is ca. 2.8 : 1 and excess reagent is removed by vacuum distillation or solvent extraction.

Aminoethylated Starches. These derivatives are produced by reaction of starch with ethyleneimine [*151-56-4*] [138] followed by acidification:

This reaction is performed with a starch slurry and typically carried out at 75 – 120 °C [139].

Cyanamide Derivatives. Cyanamide [*420-04-2*] and its dialkyl derivatives react with granular starch at pH 10 – 12 to produce iminocarbamate derivatives which can be acidified to give cationic starch derivatives [140]. This reaction is conducted under alkaline conditions

Starch Anthranilates. Starch can be reacted with isatoic anhydride at pH 7.5 – 9.0 [141].

Diazotization of the resultant amine with nitrous acid produces the desired cationic starch derivative

Cationic Dialdehyde Starch. Starch can be converted into a cationic form by initial oxidation to dialdehyde starch followed by reaction with hydrazine [*302-01-2*] or hydrazides (the reaction with betaine hydrazide hydrochloride is shown below) [142]

Granular starch is dispersed in an aqueous slurry (15 % solids) and reacted with a hydrazine or hydrazide derivative (3 – 5 % concentration) at an initial pH of 4.5. The pH drops to between 2.5 and 3.2 as the reaction proceeds at 90 – 95 °C for 2 – 3 h.

Properties. The gelatinization temperature range of cationic derivatives decreases as the DS increases [143]. Such cationic starch dispersions have increased stability and clarity compared to dispersions of the native starches from which they are derived. Also, zeta potential measurements show that these cationic starch derivatives have a net positive charge at a pH of between 4 and 9 [144].

Cationic starches react chemically with anionic dyes such as Light Green SF Yellowish or Acid Fuchsin [115]. On electrophoresis these derivatives migrate toward the cathode [145]. Commercial cationic starches typically have nitrogen contents of 0.2 – 0.4 % [146].

Uses. Cationic starches are used in the paper industry as wet-end additives and sizings, as coating binders for clay, as warp sizing agents in textiles, as flocculation agents for clay, titanium dioxide, coal, iron ore, silt, anionic starch, and cellulose, and for many other uses.

As a wet-end additive in *paper*, cationic starches increase the retention of fines and improve paper strength while also increasing drainage [147]. Cationic starches may also be used as paper sizing agents [144].

As a *coating binder,* cationic starch promotes the binding of clay to fiber [148]. In *textiles* it is a warp sizing agent [149] and provides good lubrication and yarn abrasion resistance. The ability of cationic starch to flocculate fines is seen in its use in treating raw primary sludge [150]. Its ionic nature makes it a useful *emulsion breaker* for either water-in-oil or oil-in-water emulsions [151].

3. Economic Aspects

Global Starch Production [152]. 99 % of the global starch production of is from maize, manioc/cassava, wheat and potatoes, with 74 % maize starch, 10 % tapioca starch, 8 % wheat starch and 7 % potato starch. Starch is predominantly produced in the United States, the EU, Japan, and Thailand. Production figures of the EU are given in Table 7.

Table 7. Starch production in the EU 2005 [152]

	EU*
Raw material input, 10^6 t	
Maize	7.0 (31.2 %)
Potato	8.7 (38.4 %)
Wheat	6.9 (30.4 %)
Tapioca	
Others	
Total	22.6
Starch produced, 10^6 t	
Maize starch	4.4 (46 %)
Potato starch	1.7 (18.1 %)
Wheat starch	3.4 (35.9 %)
Total	9.6

* Association des Amidonniers et Féculiers (AAF), 2006.

In small production units, mainly in Asia, starches are separated also from other starch-containing materials. These materials include: amaranth, arrowroot, banana, canna, cow cockle, faba/mung beans, kouzou, lentils, lotus roots, quinoa, sago palm, sorghum, sweet potatoes, taro, water chestnut, wild rice, and yam.

Starch Production in the EU (Table 7). The starch industry in Western Europe comprises 24 different companies with 68 plants, which produced 9.6×10^6 t of starch in 2005 with a share of 46 % maize starch (4.4×10^6 t), 35.9 % of wheat starch (3.4×10^6 t) and 18.1 % of potato starch (1.7×10^6 t).

EU Consumption of Starch and Starch Derivatives (Table 8). In 2005, 9.0×10^6 t of starch products were consumed in the EU, split into 5.1×10^6 t of starch hydrolysates (starch sweeteners), including isoglucose and polyols (57 %); 2.1×10^6 t of native starches (23 %) and 1.8×10^6 t of modified starches (20 %). 57 % of these 9.0×10^6 t were consumed in the food and 43 % in the nonfood sector.

Table 8. Consumption of starch and starch derivatives by sector in the EU in 2005*

Sector	Consumption	
	10^6 t	%
Food	5.13	57
Confectionery and drinks	2.7	30
Processed food	2.43	27
Nonfood	3.87	43
Paper and corrugating	2.52	28
Chemicals fermentation and other industrial products	1.26	14
Feeds	0.09	1
Total	9.0	

* Source: AAF 2006.

The breakdown by application areas/market sectors was as follows: sweets and drinks (confectionery, drinks, fruit processing) 30 %, processed food (convenience food, bakery, food ingredients and food preparations, dairy products and ice cream) 28 %, paper and corrugating (papermaking, corrugating and paper processing) 28 %, chemical, fermentation, and other industrial products 14 %.

Starch Production in the United States [153]**.** In 2005, 3.3×10^6 t of maize starch were produced in the USA and 3.03×10^6 t of starch products (corn starch, modified starches, dextrins) and 14.8×10^6 t of refinery products (glucose syrups, high fructose corn syrups, dextrose, corn syrup solids, maltodextrins, and fructose) were shipped in the United States. High fructose corn syrup (HFCS) 42 accounted for 4.7×10^6 t, HFCS 55 for 6.0×10^6 t of these 14.8×10^6 t. 136.6×10^3 t corn starch, 191×10^3 t modified starches derived from corn starch and 636×10^3 t of refinery products (glucose syrups, high fructose corn syrups, glucose, corn syrup solids, dextrins, and fructose) were exported.

Starch Production in Thailand [154]**.** Thailand is by far the largest producer of tapioca starch in the world. The other tapioca producing countries, such as Vietnam and Indonesia, are only of minor importance. In 2006 3.5×10^6 t of tapioca starch were produced in Thailand, 2.3×10^6 t were exported, the rest used for domestic supply. Of the exported 2.3×10^6 t 1.67×10^6 t were native (unmodified) and 638×10^3 t modified starches. The rest was exported as sago (granulated starch).

1. Introduction

Nowadays the term steel is understood to include not only all forgeable iron-based materials, but also all highly alloyed metallic materials in which the element iron (Fe) is an important component, but which are not necessarily forgeable. With few exceptions, the carbon content is $< 2\,\%$.

For over 3286 years, steel has made a major contribution to human development, e.g., in tools for cultivating the soil and processing stone and almost all other materials, as a construction material for steel and reinforced concrete structures, in transport technology, for the generation and distribution of energy, for the fabrication of machinery and equipment (including equipment for the manufacture of plastics), in the household, and in medicine. It remains, for the forseeable future, by far the most important material for the maintenance and improvement of our quality of life.

The outstanding importance of steel is the result of its ready availability and its versatility. The earth's crust contains ca. 5 wt % iron, making it the fourth most abundant element after oxygen (46 %), silicon (28 %), and aluminum (8 %). Rich deposits of iron ores are available in many parts of the world (→ Iron, Chap. 2.1.1.). Moreover, the free energy required to isolate iron from its oxidic ores is less than half of that required for aluminum [1].

The versatility of steel is due to the polymorphism of the iron crystal and its ability to alloy with other elements, forming solid solutions or compounds. The microstructure of steel in a finished component can be adjusted by means of the chemical composition, the forming conditions and a wide variety of possible heat treatments. The attainable tensile strength ranges from ca. 300 N/mm^2 for deep-drawing sheet steel (e.g., for automotive body parts that are difficult to draw) to >2000 N/mm^2 for critical components in aircraft. Tensile strengths as high as 2600 N/mm^2 are achieved in 0.15 mm diameter drawn wire for steel cord used in radial tires.

Cryogenic steels with high strength and good toughness at very low temperatures are used for the transport and storage of liquefied gases at temperatures of $<-200\,°C$. Other steels with good properties at temperatures of 650 – 700 °C and above are used in power station equipment and gas turbines.

Highly developed soft magnetic steels are essential in the construction of transformers. Steel is also used to make permanent magnets. Non-

magnetizable steels have also been developed for use in electrical technology, shipbuilding, and physics research. Wear-resistant steels are used in rock-crushing machines and in industrial stirring equipment. Machine tools, used for metal cutting, require steels of the highest possible hardness to endow stability to the cutting edge. Other steels with very good machinability have been developed and are used for the economic manufacture of complex turned parts, or for mass production on high-speed automated equipment. Chemically resistant steels are essential in the chemical and foods industries, as well as in household equipment. For the majority of steel grades – more than 2500 are available today – very good welding properties are important, and here steel has an advantage over competing materials.

Figure 1. World crude steel production 1950 – 1991

Modern knowledge of controlling the microstructure of steel, and hence its properties, offer opportunities to match steel products to new sets of requirements [2].

Unlike brick or concrete buildings, steel structures can be dismantled relatively easily. Furthermore, almost 100 % of the steel can be recovered from steel-containing products and can be remelted to yield steels of similar or higher quality. In this respect, iron and steel are superior to all competitive materials.

The great importance of steel in the world's economy is also exemplified by production figures. In the early 1900s, total world production of steel was less than 35×10^6 t/a. In 1940 it was 140×10^6 t/a. The figures for the period after 1950 (Fig. 1) indicate a surprisingly large growth in world crude steel production after World War II. Up to the mid-1970s, this was mostly due to those developed countries with the greatest rate of economic growth, such as Japan, the six founding countries of the European Community, and also the former Soviet Union. In the United States, growth had already ceased by the mid-1960s due to market saturation.

A rapid increase in steel production also took place in some Latin American countries, continuing until the mid-1980s. In many countries in Asia, Africa, and the Middle East, new steel industries were built up, or existing capacity was increased. The developments in some Asian countries during the last 16 years are remarkable (see Table 1).

Table 1. Development of crude steel production in Asian countries∗

Country	Production, 10^3 t/a		
	1975	1985	1991
China	23 903	46 700	70 400
South Korea	1 994	13 539	26 000
Taiwan	680	5 088	11 000
India	7 991	11 140	17 100

The relationship between total economic development and steel production can be seen clearly from these figures. Figure 1 also shows that world production of crude steel has stagnated since the mid-1970s, apart from the usual market fluctuations. A sharp rise in crude steel production in countries with rapidly increasing industrialization contrasts with zero or even negative growth in steel production in countries that are already highly industrialized (e.g., the United States). Several reasons can be suggested:

The steel consumption of a country is determined by the "specific market demand", i.e., production plus imports minus exports of steel products expressed in kilograms crude steel per capita. In industrialized countries, this reaches saturation at ca. 600 ± 100 kg, which can only be exceeded in special circumstances. If there are sections of industry with extremely high steel consumption (shipbuilding or automotive industries), and if these are strongly export oriented,

a value of >700 kg per capita can be reached because the exported finished products do not remain in that country. Figure 2 shows that the saturation value of 600 kg was reached as early as 1950 in the United States. Other industrialized countries reached this figure in the 1970s, and this reduced the growth of steel production. Also, the expansion of the steel industry in countries which had been importing rolled steel made it impossible for steel exports from the industrialized countries to grow. Extrapolation of the Figure 2 into the 1980s is problematical because the figure "kilogram crude steel per capita" is now no longer comparable with figures up to ca. 1975 due to technical developments (described below) in rolled steel products.

Figure 2. Specific market demand for crude steel (production + imports − exports) [1]
–·– = United States; – – – – = Federal Republic of Germany; ····· = former Soviet Union; —·— = Japan; — ··— = World

From the second half of the 1960s, use of the continuous casting process in steelworks increased, approaching 20 % by 1975 worldwide. By 1991, the proportion of continuously cast steel reached 67 % worldwide. This process gives an increase in yield of ca. 12 – 15 % of crude steel for rolled steel products, compared with ingot casting. Hence, up to 15 % less crude steel is required to produce the same amount of rolled steel product for the steel processing industry. Other improvements in yield productivity in steel plants and in steel- consuming industries also reduced the consumption of crude steel without jeopardizing the use of steel for a particular end product.

Table 2 lists all countries with a crude steel output of more than 10^6 t/a during 1991 and 1992 and gives the percentage of continuously cast steel.

Table 2. Countries with a crude steel output $>10 \times 10^6$ t/a (1991 and 1992) ∗ with portion of continuously cast steel shown

Country	Production, 10^6 t/a		Portion of continuously cast steel, %	
	1991	1992	1991	1992
Former Soviet Union	132.8	116.8	17.7	17.1
Japan	109.6	98.1	94.4	95.4
United States	79.7	84.3	75.7	78.9
China	70.4	80.0	26.5	30.0
Germany	42.2	39.7	89.5	92.0
South Korea	26.0	28.0	96.4	96.8
Italy	25.1	24.9	95.1	96.1
Brazil	22.6	23.9	56.0	58.6
France	18.4	18.0	95.0	95.2
India	17.1	18.1	14.3

Spain	12.9	12.3	91.8	93.2
Czechoslovakia	12.1	11.1	17.0	21.9
Belgium	11.3	10.3	92.2	93.9
Taiwan	11.0	10.7	94.6	94.9
Poland	10.4	9.8	8.6	9.1

∗ Source: International Iron and Steel Institute 1992.

In 1978, however, for the countries represented in Figure 2, the percentages of continuously cast steel were:

Former Soviet Union	9.5 %
Japan	46.2 %
United States	15.2 %
Federal Republic of Germany	38.0 %

The large differences between the 1978 and 1991 figures, means that comparison of the number of kilograms crude steel per capita is of questionable value.

Below a continuously cast steel portion of ca. 85 – 90 % "kilograms crude steel per capita" is an indication of the state of modernization of the steel industry of a country. Above this range, the production program and the proportion of steel products not produced by continuous casting (e.g., steel castings, heavy forgings) play an important part in crude steel production. Only countries with a crude steel output in 1991 of max. 10^6 t/a (e.g., Switzerland and New Zealand) produce 100 % of their steel by continuous casting.

A further reason for the absence of the usual growth in crude steel production in the 1960s in

the industrialized countries, must be attributed to the development of higher strength steel grades. In the last 15 – 20 years, these grades of steel have been increasingly used by steel processors. Especially in the motor vehicle industry, high-strength steels have been used to improve constructional design through weight reduction. Consequently, there is a decrease in the amount of steel used, in addition to that achieved with the replacement of steel by competing materials such as aluminum or plastics.

When assessing the technological and economic significance of steel, it is interesting to examine the different finished steel products and how their share of the total production of rolled steel has changed over the years. There are two groups: "long products" (i.e., beams, steel shapes, steel bars, railway-track material, piling sections, and wire rod) and "flat products" (i.e., plates, sheets, strip-steel and universal-plate; see also Section 6.2.1).

In 1870 3×10^6 t of railway-track material accounted for 43 % of total world production of rolled steel products (Fig. 3), while in 1991 the output of railway-track material, which underwent a threefold increase to 9×10^6 t, accounted for barely 1.2 % of total production. In modern industrialized countries, 60 – 70 % of rolled steel production consists of flat products, mainly hot- and cold-rolled strip and sheet, coated sheet, tinplate and electric sheet, all with thicknesses in the range of 0.15 – 3 mm. The production of cold-rolled stainless steel strip has increased sharply during the last 25 years, as shown in Figure 4.

Figure 3. World production of steel for railway-track material lines
Solid line: total production of railway-track material; Hatched area: railway-track material as percentage of the total world production of rolled steel

Figure 4. Production of cold-rolled stainless steel strip by western countries

There is intensive world trade in products of the steel industry, especially among major steel producing countries. Only in a few cases does this involve special products or special steel grades, for which some producers have a leading position. International competition is severe, and producers must offer consistently high-quality products. The large producers have therefore built up comprehensive quality assurance systems over many years, conforming to ISO Standard 9002 and local regulations such as ASME in the United States, Lloyds Register in the United Kingdom, and TüV in Germany. The aim is to control all steps of the manufacturing process, and to use statistical methods to ensure that the finished product has the desired properties, dimensional tolerances, and a defect-free surface finish. The intensive testing of finished products that was formerly carried out can then be largely dispensed with, and replaced by the testing of random samples, the results of which form part of the control loop.

Such quality-assured production is a prerequisite for the direct processing of sheet coils on automatic press lines without any inspection (even for exposed autobody parts).

A further important aid to international trade in steel is the existence of common standard specifications and terms of delivery. Specifications for steel products have been formulated by ISO over many years. However, these are often only the first steps toward harmonization of the various interpretations and technical possibilities. In Europe, since 1986, EN Standards for all steel products and testing methods have been

Figure 5. Furnace reactions for the production of iron by the direct method in a bloomery hearth furnace (after D. HORSTMANN)

compiled by the ECISS (European Committee for Iron and Steel Standardization). These standards must be adopted via CEN (Comité Européen de Normalisation) into the national standards of all European nations. They will certainly achieve importance outside Europe, too.

2. History

2.1. From Prehistoric Times to the Middle Ages

2.1.1. Native Iron

Since the earliest times, humans have used iron, the second most abundant metal in the earth after aluminum. It was first discovered in the form of the native element, which occurs only rarely as tellurian iron of volcanic origin, and mainly as meteoric iron. The Egyptians, Sumerians, Khatti, and Hittites must have had knowledge of its origin, as they called it ore, or metal, from heaven. Meteoric iron can be identified from its high nickel content (ca. 5 – 25 %), and the typical Widmanstätten structure, formed on solidification. The oldest known examples of worked meteoric iron are beads from Gerzeh (3500 B.C.) and a dagger from Ur (3000 B.C.)

2.1.2. Iron from Ores

It is not known when, where, or how iron was first deliberately produced from its ores. It is often said that the technique of extracting iron was developed from observations made during copper extraction, and that the idea suggested itself simultaneously in many places with a long tradition of copper smelting. A geographical analysis can be carried out from linguistic similarities, archeological finds, and documents. According to present knowledge, iron was first smelted in eastern Asia Minor and northern Mesopotamia around 2000 – 1500 B.C., and possibly also in the plains north of the Caucasus. As the Chinese were the first to produce a high-carbon, high-phosphorus (up to 7 %) liquid castable iron, it is conceivable that they also succeeded in winning iron from its ores at a very early date. Around 500 B.C., knowledge of iron winning spread through Asia Minor to North Africa, parts of Asia, and all of Europe.

2.1.3. Technology of Iron Production

At first, the iron was smelted in a bloomery fire, later in a bloomery hearth furnace, and crucibles. The iron ore was charged with charcoal, and later, according to the type of gangue material, with other fluxes, into a hearth or the shaft of a furnace. The charcoal was burned by a blast caused either by a natural draught (convection) or by hand- or foot-operated bellows. The rising combustion gases dry the materials (Fig. 5), and reduce the ore at ca. 900 – 1100 °C, forming a primary slag of wustite (FeO). From the gangue, a molten liquid slag forms, from which, in a further reduction stage, pure solid iron separates out, with formation of secondary slag. Since no appreciable carbonization of the iron takes place, it does not liquefy, even in the lower part of the furnace (temperature ca. 1200 –1300 °C). The product, the so- called bloom, consists of iron with slag inclusions and residual charcoal. These were separated, and the blooms were reheated and forged into bars. Up to the late Middle Ages iron, or rather steel, was obtained exclusively by this process directly from the ore, except in China. As a result of improved bellow technology, the furnace volume grew. About 900 years ago, this development culminated in bloomery furnaces with reached heights of 4 m, thanks to the wind pressure from waterwheel-powered bellows.

In addition to the technique of iron winning, knowledge of the properties of iron and how to modify them also developed empirically and involved little understanding of cause and effect, even up to the 1700s. It was recognized at an early stage that iron could be hardened by heating (with carburization) followed by rapid cooling. As early as the 900s B.C. crucible furnaces were used for carburizing iron in Gerar, Palestine. Moreover, the technique of combining high- and low- carbon steels was used to achieve a desired combination of properties, such as toughness and hardness, e.g., in the production of Damascus steels.

2.2. From the Middle Ages to the 1800s

In the 900s, technology was revolutionized by the waterwheel, with far-reaching effects on iron production. Water power became more important than the availability of ore when choosing the location for iron smelters. Thus, the preferred smelter location changed from the mountains, with proximity to ore and wood, to the river valleys, with their availability of flowing water.

The blast produced by water-driven bellows enabled larger furnaces to be operated. These were originally bloomery furnaces, but became flowing furnaces in the 1100s and 1200s. Water power was also used to operate tail hammers, lift hammers, etc. This development took place almost simultaneously in the alpine regions, and in western and northern Europe, which is not surprising in view of the extensive trade in medieval Europe. The historical development of iron and steel production equipment, and the growth of total world steel production, is summarized in Figure 6.

2.2.1. Bloomery Furnaces

In principle, bloomery furnaces were simply an increase in furnace size. They were up to 6 m high, operated batchwise, and produced a bloom up to 100 kg after ca. 15 h operation. The earlier furnaces produced a bloom of only 20 kg. Refining the blooms is a two-stage operation: a metallurgical treatment in the refining furnace (slag removal, homogenization, and, if necessary, decarburization); followed by hammering into bars, and a mechanical mixing operation in which bars of steel of various qualities are hammered together, forming a fairly uniform product. Bloomery furnaces, like the small Corsican and Catalan forges that used the same principle, were still producing a small fraction of the total production up to the 1800s.

2.2.2. Blast Furnaces

Together with the use of water power, the main revolution in iron smelting in Europe was the discovery of the two-stage indirect production of steel – the method still used today. In the first stage, liquid pig iron with a high carbon content is produced in the blast furnace. In the second stage, this pig iron is decarburized and refined to steel in a finery fire. The improved air pressure and flow rate enabled furnace temperatures $> 1200\,°C$ to be achieved. The furnace volume

Figure 6. Development of steel production processes and forming, with a graph of annual steel production [13]

could be increased, leading to a longer dwell time for the burden as it passed down the furnace shaft. This led to improved reduction of the iron ore (the yield increasing from 50 to > 85 %), and carburization of ca. 2.5 – 5.0 %. The lowering of the melting point led to the production of liquid pig iron for the first time, and considerably improved output. The furnaces could be charged without interrupting the process, and the liquid iron was directly cast into finished products (furnace plates and cannon balls) or bars for sale or captive processing in the finery shown. Here, the crushed pig iron was smelted in the finery hearth and decarburized under an oxidizing slag. Steel blooms were formed from the molten metal as it thickened, and these were then hammer forged into semifinished products. The furnace workers were able in some degree to control the properties of the product, but their empirical knowledge was mainly limited to processing certain types of ore or pig iron. An example is Osemund iron, which was ductile and, therefore, used for wire production. Steel production and processing centers were established in Austria, France, Belgium, United Kingdom, Germany, Sweden, and Russia. Iron production in Europe increased from 20 000 – 30 000 t/a (when small blast furnaces were introduced in ca. 1200 A.D.) to ca. 150 000 t/a at the inception of coke-based metallurgy in the mid-1700s.

2.2.3. Metal Shaping

Up to the 1500s, iron was processed only by forging and drawing, but, as the indirect method of iron production became widespread, water-powered rolling mills came into use. However, production rates of the blast furnace, the finery fire, and the hammer forge were roughly comparable, and hot rolling was unable to produce a product comparable to forged steel. Therefore,

hot rolling was only occasionally used for the treatment of forged material. Its most important application emerged later in the so-called iron-splitting works, in which strips were produced from steel sheet (e.g., for nail production). These operations were common in almost all iron-producing countries until the mid-1600s.

The range of rolled products increased during the early 1700s. In Sweden, Christoph Polhems was able to produce rolled steel with various profiles for knife blades and files. In England, John Hanbury produced thin steel sheet on a pillar rolling mill for tinplate manufacture. This type of equipment was being used for the manufacture of steel sheet for steam boilers by 1764 at the latest. In the same year, John Paynet obtained a patent for the preforming of flat bar by grooved rolls, and John Westwood was awarded a patent for cold rolling in 1783. In 1778, the Frenchman Fleur described a four-stand rolling mill with closed passes which he used for wire production. Proposals for continuous rolling were also published.

Apart from the iron bearings, rollers, cutting rings, and spacers, the rolling mills were constructed of wood. In the mid-1700s, gear wheels and pillars were all of cast iron. Energy was supplied by one or two waterwheels, depending on the size of the rolling mill. The upper and lower rolls were generally driven separately, but pinion stands were also used. The mechanical and thermal stresses on the rolls were large. At first the rolls were made by welding a hardenable steel sheet around the forged roll body. Later, cast iron rolls were used. A further development was the casting of steel around a bar which was used as roll neck.

Rolling mills did not yet replace hammer forges, as their use was limited by the quality of the engineering and the availability of power.

2.3. The Industrial Age

The 1700s saw the development of mechanical power (steam engines), transport (railways, bridges), and the increasing use of machinery, all of which was made possible only by the almost complete replacement of wood by steel as a construction material. The resulting enormous increase in demand provided the impetus for the development of new methods for bulk steel production.

Iron and steel were produced exclusively from charcoal up to the 1700s, but by the end of the century, processes had been developed that enabled charcoal to be replaced by coal. These were coke-based metallurgy and the crucible steel and puddling process, supplemented by the development of the hot rolling process. They formed the basis for the economic mass production of this universal construction material, which satisfied the broad requirements of the approaching industrial era.

During the preindustrial epoch, most of the improvements in steel production methods took place on the European mainland, but the inventions that led to the industrial revolution were made in Britain. These are linked with the names Abraham Darby II (1711 – 1763) who introduced the first true coke-based blast furnace (1735) and the first use of steam engines (1742) to steel production; Benjamin Huntsman (1704 –1776) – crucible steel casting (1742); Henry Cort (1740 – 1800) – development of the puddling process (1783 – 1784); Jean Beaumont Neilson (1792 – 1865) – hot air blast (1829); James Nasmyth (1808 – 1890) – steam hammers (1839), first installed at Creusot (1841); Henry Bessemer (1813 – 1898) – acid air refining process (1856 – 1860); Sidney G. Thomas (1850 – 1885) and Percy C. Gilchrist (1851 – 1935) – basic refining process (1878); Wilhelm Siemens (1823 1892) and Friedrich Siemens (1826 – 1904) – regenerative heating (1861). Important innovators in other countries include Faber du Faur (1786 – 1855) – blast heating (1832); Pierre Emile Martin (1824 – 1915) – open hearth process (1864); Rainer Daelen (1813 – 1887) – universal mill stand (1848); Charles Morgan (1831 – 1911) – rolling mill technology (from 1865); George Bedson – continuous rolling mills (1860); Reinhard Mannesmann (1856 – 1922) and Max Mannesmann (1857 – 1915) – rolling seamless tubes (1890); Paul Hérault (1863 – 1914) – electric arc furnace (1900).

These innovations were gradually introduced into the most important iron-producing countries, including the United Kingdom, Belgium, France, Germany, Austria, and the United States, all of which made their own contributions to

the further development of iron and steel technology. Historically, the last pioneering inventions are the basic oxygen steelmaking process, secondary metallurgy, and continuous casting, which were developed in the 1940s and 1950s.

Figure 7. Puddling furnace with iron hearth and cast iron shell (1830) [14]

2.3.1. Pig Iron Production

The cradle of coke-based metallurgy was Coalbrookdale, where Abraham Darby I (1678 – 1717), who had invented the process of casting iron in sand molds in 1707, probably began the production of pig iron using coke in 1709. His son, Abraham Darby II, was the first to operate a blast furnace fueled entirely with coke in 1735. Coke-based metallurgy spread to the rest of the United Kingdom only slowly at first (in 1750, 3 of 74 blast furnaces were coke based; in 1760, 14 of 78; in 1791, 85 of 107). The real breakthrough came with the development of the puddling process for converting pig iron into steel, the production rate matching that of the iron-making process. In mainland Europe, these new technologies were adopted in a dilatory fashion. The first coke-based blast furnaces were operated in France by Creusot in 1785, and in Germany in Gleiwitz (1796). Whereas pig iron production in the U.K. was almost exclusively based on coke in the early 1800s, Germany reached this stage only at the end of the century.

From the early 1800s, coke-based metallurgy was accompanied by research and development, with increases in productivity and profitability. Developments were mainly concerned with the design and size of blast furnaces, including blast and power supplies, increasing the efficiency of energy utilization, and improving yield and quality through better understanding of the metallurgical processes, enabling the control of the blast furnace process to be improved, culminating in computer control.

This development can be demonstrated by data for selected blast furnaces (Table 3).

2.3.2. Steel Production

After the invention of the pig iron furnace, forgeable and hardenable iron (steel) was produced both from almost carbon-free wrought iron and from highly carburized pig iron.

Wrought iron, in the form of soft iron bar, was carburized to steels with a higher carbon content from the early 1600s (originally in 1601 in Nuremberg by Paulus Hannibal) by heating in carbon-containing powders with exclusion of air. This so-called cemented steel had a wide range of uses, e.g., for springs, knives, and files. In the 1700s, the steel industry in Sheffield was founded on the use of this process for the treatment of imported Swedish iron bars. Here, 205 cementation furnaces produced almost 80 000 t steel in 1862. The last of these went out of production in 1951. This cemented steel (blister steel), which was inhomogeneously surface-carburized and blistered, was homogenized by hammering out (sometimes repeatedly) bundles of cemented steel rods to form "shear steel". Although this led to some equalization in material properties, this steel met the increasing quality requirements only to a limited extent.

2.3.2.1. Crucible Steel

The first decisive step toward production of nearly homogeneous and slag-free steel was taken by Benjamin Huntsman in 1740, with the production of liquid steel by melting together cement steel with added bar iron and

Table 3. Development of blast furnaces

Year and location	Hearth area, m^2	Coke consumption per tonne iron, kg	Iron output, t/d
1796 (Gleiwitz)	0.3	3500	1 – 2 (later 4)
1801 – 1815 (U.K.)		2500	5 – 7
1856 (Hasslinghausen)	3.6	1600	20 – 23
1880 (United States)	8.8	1510	120
1901 (United States)	15.3	1000	464
1929 (Bruckhausen)	33.2	740	1100
1993 (Schwelgern 2)	174.9	480 ∗	10 600

∗ Fuel consumption.

glass in refractory crucibles. The productivity of this process was later increased by improvements to the crucible material (graphite). Crucible steel opened up completely new perspectives. The steel was both castable and forgeable. By pouring the contents of several crucibles into one mold, ingots and castings of large mass were produced for the first time. As alloying was possible, steel developed into a universal construction material. As this process was more economical than the production of shear steel, it spread relatively rapidly.

2.3.2.2. Puddled Steel

Pig iron from the small furnaces that later developed into blast furnaces was cast, either directly or after remelting, in a cupola furnace to give finished products (e.g., machine parts, construction elements, household articles) or was decarburized to forgeable steel. The steel produced by decarburizing coke pig iron tended to be brittle (owing to sulfur and phosphorus) compared with that produced from charcoal pig iron. The low productivity of decarburization in open charcoal-fired finery fire became a problem, owing to the increasing rate of production of pig iron; steel producers sought a more effective fining process that would operate with coal or coke. The breakthrough was achieved by Henry Cort with his patented method (1783 – 1784) for producing wrought steel – the puddling process. This consisted of remelting the pig iron and fining with the combustion gases from the coal- or coke-fired reverberatory furnace (Fig. 7), followed by mechanical slag removal and welding together of the lumps of steel by means of a steam hammer or squeezer to form blooms of very variable chemical analysis. These were rolled in a rolling mill to form "crude" flat iron. To produce a homogeneous rolled steel, fagots of flats were placed together, heated in a welding furnace, and rolled. This step could be carried out several times. The process met all requirements of the time, i.e., increase in productivity (tenfold), replacement of charcoal by coal, and reduction of production costs. It spread relatively rapidly into all iron-producing countries. In Germany, the first puddling plant was started in the Rasselstein iron works in 1824. The last puddling operation ceased in the 1940s.

2.3.2.3. Ingot Steel

With time the puddling process also became unable to meet the increasing demand for steel. In 1856, Henry Bessemer invented his autothermic air refining process, which made it possible for the first time in the history of iron production to convert pig iron directly into liquid steel, increasing productivity by a factor of 70 (Fig. 8). In the Bessemer process, molten pig iron is blown with air from below in a tiltable converter. The molten metal is decarburized by oxidation, which also removes silicon and manganese. The heat liberated causes the temperature to rise well above the melting point. As the original lining of the converter was acidic, only low-phosphorus pig iron could be treated, and the use of the process was therefore limited. This problem was solved in 1878 by Sidney G. Thomas and Percy C. Gilchrist by the use of basic dolomite as converter lining. Thus, phosphorus could be removed by means of a basic slag, which later became an important fertilizer (Thomas slag). The Thomas process was widely used, especially on the European mainland, where the ores, e.g., minette (oolitic iron

ore), often have a high phosphorus content. In Germany, the first Thomas steelwork was operated in 1879. The last one was shut down only recently.

Figure 8. Bessemer steel works with circular casting pit (Friedrich Krupp, Historical Archive, 1970)

Ingot steel production by air refining became the most important steel production process worldwide with the introduction of the basic oxygen (LD, Linz – Donawitz) process in 1952.

In parallel with the air-refining processes, the allothermic hearth process was also developed. In 1864, F. and W. Siemens together with E. and P. Martin succeeded in melting pig iron and steel scrap, using regenerative heating in a reverberatory furnace. The Siemens – Martin process at first achieved great importance for the recovery of scrap. Later, pig iron was melted with iron ore, with or without the addition of steel scrap. Until the breakthrough achieved by the oxygen refining process, this was the most important steel production process, accounting for up to 60 % of all steel production.

After the 1850s, electrical energy became available, and attempts were made to build electric hearth melting furnaces. The electric arc furnace developed by Héroult was especially successful, and was first operated full-scale in Germany in 1906. Although it was initially used for the production of special steels, it is now increasingly used only for steel melting, owing to the availability of cheap electricity, and the introduction of secondary metallurgy.

2.3.3. Rolled Steel Production

2.3.3.1. Puddled Steel and Steam Power

Following the discovery of (1) the puddling process, which enabled iron to be converted to the finished product by a rolling operation; and (2) the introduction of the steam engine, the technology of the rolling mill became an integral part of steel production.

Although this new technology was quickly adopted and further developed in England, this only happened in a few places, owing to the high cost of steam engines. As early as 1784, J. Wilkinson started the first steam-driven rolling mill in his iron works in Bradbury, and replaced the hammer forge by a blooming mill with self-adjusting rolls. This was patented in 1792. There followed improvements in rolling equipment, by making it more powerful (the production of cast machine components of everincreasing size, and the development of techniques for gearing and driving). This can be seen from the dimensions of the rolls, which reached diameters of 300 mm and body widths of 1200 mm.

On the basis of these new methods, England's iron and steel industry occupied a leading position throughout the 1800s. Continental iron producers were able to adopt the new technology only later, sometimes only by industrial espionage or by the enticement of specialist personnel. The major economic incentive was the immense demand for railway track.

The plan view (Fig. 9) of the rolling mills at Couillet (1835) shows the layout of a typical works of that time. The puddling and rolling plants formed a single unit. The steam engines were at the heart of the ironworks. They drove the puddling plant and rail mill, the three-stand sheet mill, the six-stand bar mill, a two-stand mill for rolling – cutting, and an auxiliary plants. This works produced ca. 10 000 t rolled steel in 1840.

2.3.3.2. Ingot Steel and Mass Production

The further development of rolling mills took place against the background of the developing mass production of ingot steel. The first

product became the cast steel ingot. Developments took place particularly in drive technology and the construction of specialized rolling stands and mills (and also auxiliary machinery and reheating furnaces which are not considered in this article). The realization of reversible operation of rolling stands driven by steam engines was the trigger for the further improvement of the driving machinery. In the 1870s, hydraulic friction coupling for reversible operation was successfully designed and constructed. However, almost 30 years of development were required before the problem of reversing the steam-driven rolling mill engine was solved by Clemens Kisselbach in 1891. The use of electrical driving machinery, which began in 1900, increased, especially after the invention of the reversible electrically driven rolling mill engine by Ilgner in 1902.

The design and construction of rolling mills and plant was driven by the demand for mass production, with increasing throughput, size, and range of products. The American, John Fritz, in 1857, eliminated the need for reversible rolls by designing and successfully operating a three-high rolling stand for rail production. In 1848, Rainer Daelen built the first universal rolling stand, which found wide application, especially in the United States. Using this equipment, finishing of I-beams was first achieved in 1866. In 1883, I. J. Seaman and H. Sack separately applied for patents for universal rolling mills for rolling beams. Wire and rod steel products were rolled in open rolling trains. The introduction of mechanical loopers in 1877 led to a considerable increase in performance. At the end of the 1860s, G. Bedson constructed the first continuous finishing train for wire, with 16 alternately horizontal and vertical rolling stands. This type of train was further developed, mainly by C. Morgan in the United States. In 1905, in Gary, Indiana, the first train operating completely continuously from ingot to finished product was commissioned. From the early 1800s, a large number of proposals for the production of seamless tubes by rolling were made. However, the breakthrough was an invention by M. and R. Mannesmann, in which a hollow body was produced by skew rolling (1886), with subsequent expansion to form a seamless thin-walled tube in the Pilger step-by-step-type seamless tube rolling mill (1890). The development of flat rolling aimed to increase the dimensions of strip and sheet, the weight of charge,

and productivity. The United States led the way, and the first continuous hot strip mill went into operation during the 1920s. These mills constitute as important a development for modern steel production as the oxygen steelmaking process, secondary metallurgy, and continuous casting.

3. Crude Steel Production

3.1. Raw Materials

The following iron-bearing materials are used for crude steel production (Table 4) [16]:

1) Molten iron from blast furnaces (hot metal), mainly used for steel production by the basic oxygen furnace (BOF) process
2) Scrap, sponge iron, and solidified blast-furnace iron (pig iron), mainly used for melting steel in electric furnaces

Another important raw material is lime for slag formation. Alloying elements, such as chromium, nickel, molybdenum, titanium, vanadium, and niobium, and elements used as deoxidizing agents (e.g., manganese, silicon, and aluminum) are not discussed in detail here.

The most important iron-bearing material is hot metal. Of the total world crude steel production of 770 – 720 t/a in the early 1990s, ca. 60 % was produced from hot metal obtained by reducing iron ore, and ca. 40 % from steel scrap.

Steel scrap is of increasing importance as a raw material because of the lower primary energy consumption and lower CO_2 emissions, compared with the blast furnace – converter production route. Figure 10 compares the total specific primary energy consumption per tonne of steel produced from ore with that for steel produced from scrap [17].

3.1.1. Hot Metal

Hot metal is produced by reduction of iron ore in a blast furnace. Modern furnaces produce 5000 – 12 000 t/d. Immediate transfer of the hot metal to the converter for refining to crude steel requires the blast furnace and the steelworks to be in close proximity.

Iron ore is charged to the blast furnace in lump form or as agglomerated fine ore (sintered or pelletized), and reduced. Coke and injected coal are used as reducing agents, and these react with the hot air blast, liberating energy. The molten product, known as hot metal, separates from the liquid slag. It can be pretreated before transfer to the steelworks, to reduce the content of undesired accompanying elements such as sulfur, silicon, and phosphorus.

Various types of hot metal are produced, depending on the composition of the ore fed to the blast furnace (burden) and the method of furnace operation. They include low-phosphorus hot metal, (Thomas) hot metal (high in phosphorus), and foundry hot metal (high in silicon). The chemical compositions of several grades of hot metal are listed in Table 5.

Low-phosphorus hot metal is important for steelmaking. Typical temperatures for tapping the blast furnace are 1350 – 1450 °C. Carbon content is typically high (4 – 4.5 %), as is sulfur content, these elements being picked up from the coke and the injected coal. A pretreatment of the hot metal, e.g., with lime – magnesium mixtures, reduces the sulfur content from ca. 0.040 % to < 0.010 %.

Pig iron is also used to a limited extent as an iron-bearing material for steel production involving melting; the hot metal, after tapping from the blast furnace, is cooled in sand molds to form pigs which can be used like scrap in steel production.

Hot metal is produced not only by the blast furnace method, but also in coke-free processes in smaller units by smelting reduction, e.g., the Corex process, which produces 1000 – 2000 t/d [18].

3.1.2. Scrap

Steel scrap is traded worldwide [19]. It is mainly melted in electric furnaces, but to a limited extent is also added as a cooling agent to converters used in steel production by blowing processes.

In 1992, ca. 350×10^6 t steel scrap was used worldwide for steel production, the specific scrap consumption being ca. 445 kg per tonne of crude steel. Specific scrap consumption differs widely between countries, depending on the structure of the steel industry [20], [21]. In Italy, where the proportion of electric steel production

Table 4. Properties of hot metal, sponge iron, and scrap [16]

	Hot metal	Sponge iron	Scrap
Raw materials	poor to rich ores, low or high in phosphorus	ores with low gangue content	internal scrap production scrap collected scrap
Availability	almost unlimited	limited to low gangue ores or pellets	depends on steel consumption and crude steel production
Production and processing	classification, sintering, pelletizing blast furnace	classification or pelletizing shaft furnace rotary furnace retort fluidized bed	shears (cutting – burning)
Primary energy consumption (GJ/t)	14	12 (shaft furnace)	0.6 (shredder)
State of aggregation	liquid	solid	solid
Storage and transport	severely limited	special techniques may be necessary (e.g., briquetting)	good
Type of furnace using this material	oxygen-blowing furnace (BOF) (electric furnace)	electric furnace (as cooling agent in oxygen furnace)	electric furnace Siemens – Martin furnace (as cooling agent in oxygen furnace)
Price	depends on production costs	depends on production costs, market price, or agreed price	market price
Chemical properties			
Composition	constant	constant	variable
Unwanted elements	sulfur phosphorus (depends on application)	none phosphorus (depends on application)	depends on process
Type of gangue		depends on ore	
Physical properties	liquid	bulk material	variable shredded scrap (in bulk)

Thermal conductivity		low	high

Figure 10. Comparison of total specific primary energy consumption for steel products made from ore and scrap [17]
∗ Including primary energy consumption for generating electricity in thermal power stations, and energy-intensive materials (oxygen, steam, compressed air, cooling water, etc.). ∗∗ Including added scrap for cooling.

Table 5. Characteristic compositions of grades

Type of pig iron	C, %	Si, %	Mn, %	P, %	S, %
Low-phosphorus	4.0 – 4.5	0.30 – 0.70	0.20 – 0.70	0.05 – 0.12	0.03 – 0.06
High-phosphorus	3.2 – 4.0	0.30 – 0.70	0.25 – 1.20	1.50 – 2.20	0.03 – 0.06
Foundry	3.5 – 4.2	1.80 – 2.50	0.70 – 1.00	0.50 – 0.70	0.03 – 0.06

is 50 %, the proportion of scrap used, ca. 650 kg per tonne of crude steel, is naturally larger than in Germany (ca. 380 kg/t), which has 21 % electric steel production (Fig. 11).

Figure 11. Average specific scrap consumption for crude steel production in various countries [21]

The total quantity of scrap handled on world markets is ca. 50×10^6 t/a. A survey of the most important exporting and importing countries is given in Table 6. The price of scrap fluctuates widely, depending on supply and demand. Figure 12 gives an example of the fluctuations in the price of a particular grade of scrap in the Ruhr region.

Figure 12. Variations in scrap prices since 1978 [20]

Figure 13. Variations in the specific amount of internal scrap produced in various industrialized countries as a function of the percentage of strand casting [22]

Scrap is classified according to its origin: internally recycled scrap; production scrap from the steel processing industry, also known as new scrap; and collected scrap, also known as old scrap.

Internally Recycled Scrap. Improvements in the utilization of materials and technologi-

Figure 14. World crude steel production, with a forecast of old scrap availability up to 2015 [20]

cal changes, e.g., the introduction of the strand casting process, have steadily reduced the availability of internally recycled scrap (Fig. 13) [22].

New and Old Scrap. To meet the requirements of steelworks, internally recycled scrap is supplemented by the purchase of new and old scrap. To maintain steel production quality, the quality of these purchased materials is controlled by lists of scrap grades. Criteria include the metallic iron content (e.g., $> 92\,\%$), the lump size, the bulk density (e.g., $> 0.9\,\mathrm{t/m^3}$), and the density of bundles (e.g., $> 1.3\,\mathrm{t/m^3}$).

Current proportions are ca. 50 % from old scrap, 15 – 20 % from new scrap, and 30 – 35 % from internally recycled scrap.

The quantity of scrap available worldwide depends on the quantity of crude steel produced, although there is a time delay. Whereas internally recycled and new scrap are immediately returned to the system, an average of ca. 70 % of used steel products are returned as old scrap after ca. 20 years [19], [20]. On the basis of this assumption, H. W. Kreutzer has shown how the total world supply of old scrap has changed with time (Fig. 14). In line with steel production figures which increased steadily in former years, the availability of old scrap at first continues to increase, but then levels out after ca. 20 years.

It is important that scrap should not introduce unwanted elements into the steel, thereby impairing its quality. Pretreatment of the scrap by size reduction and sorting, e.g., with the aid of a shredder, is therefore very important. It is essential not to introduce elements that cannot be removed from the crude steel, or whose removal is costly, e.g., copper, nickel, molybdenum, or tin. In some steel products, a copper content of 0.40 % is tolerable, but in high-quality products, e.g., thin steel strip, the copper content is normally $< 0.01\,\%$. Therefore, when recycling scrap automobiles, copper- containing components such as electric motors and cables must be stripped out before scrapping. On the other hand, when zinc- coated car bodies are recycled, the zinc becomes concentrated in the steelworks dust, and can be easily recycled, if the levels of zinc in the dust are high enough (ca. $> 20\,\%$). So far, this has been achieved in electric steelworks owing to the high input of scrap [23]. The zinc is recovered from the dust in nonferrous metal smelting works.

Table 7. Residuals in steel and its raw materials [24]

	Cu + Sn + Ni + Cr + Mo, %
Typical maximum residual limits of carbon steels	
Tinplate for draw and iron cans	0.12
Extra deep drawing quality sheet	0.14
Drawing quality and enameling steels	0.16
Commercial quality sheet	0.22
Fine wire grades	0.25
Special bar quality	0.35
Merchant bar quality	0.50
Typical residual content of charge materials	
Direct reduced iron	0.02
Pig iron	0.06
No. 1 factory bundles	0.13
Bushelling	0.13
No. 1 heavy melting	0.20
Shredded auto	0.51
No. 2 heavy melting	0.73

Table 7 shows the maximum tolerable total content of Cu, Sn, Ni, Cr, and Mo for a number of steel products, and some typical concentrations of these elements in the raw materials pig iron, sponge iron, and five different types of scrap.

3.1.3. Sponge Iron

Another solid raw material for the steel industry is sponge iron, also known as DRI (direct reduced iron). Because of its purity and suitability for controlled feeding, it is becoming of increasing importance.

Sponge iron is produced by reduction of iron ore in the solid phase, by means of (1) reduction gas (obtained from natural gas with varying hydrogen and carbon monoxide content); or (2) coal. Of the direct reduction processes listed in Table 8, the Midrex and HyL processes are the most important. Gas reduction processes account for 92 % of world sponge iron production. Direct reduction processes are operated where cheap energy is available (natural gas, coal), e.g., Mexico, Venezuela, Saudi Arabia, Iran, Malaysia, Indonesia, India, and South Africa.

Table 8. Processes for the direct reduction of iron ores

Reduction by gases	Reduction by solids
Shaft furnace:	Rotary kiln:
Midrex	SL/RN
HyL III	Krupp – Codir
Fluidized bed:	Rotary hearth furnace:
FIOR	Inmetco
Iron carbide	Fastmet

Figure 15. Growth of production capacity and production of sponge iron [25]

Figure 15 shows the growth of the capacity and production rate of sponge iron [25]. In 1993, total production was 23.9×10^6 t while capacity was ca. 35×10^6 t, i.e., production plants were only 68 % utilized. A further increase in world sponge iron capacity of at least 12×10^6 t/a is forecast for the year 2000.

The sponge iron produced is mainly melted in adjoining steelworks, so that amounts available on the world market are limited. Approximately 3.4×10^6 t sponge iron was exported in 1992 [26]. However, there is an increasing trend toward the construction of "merchant plants", e.g., in Malaysia and Venezuela.

These types of sponge iron could be of great interest for reducing levels of unwanted elements by replacing some of the scrap used in the production of scrap-based, high-grade steel products, especially flat products produced in minimills.

Table 9. Chemical composition of sponge iron [25]

	Midrex	SL/RN
Fe, %	91 – 93	90.4 – 93.7
Metallic Fe/total Fe, %	92 – 95	92 – 93
SiO_2, %	2.0 – 3.5	2.4 – 5.8
Al_2O_3, %	0.5 – 1.5	1.8
CaO, %	0.2 – 1.6	0.05 – 0.3
MgO, %	0.3 – 1.1	≤ 0.05
C, %	1.0 – 2.5	0.1 – 0.2

Because trade in these materials has so far been small, no lists of grades or general regulations exist for sponge iron supplies, such as apply to scrap. Important characteristics include the total iron content, the ratio of metallic iron to total iron, the gangue content, and the carbon content. As all the gangue constituents report to the sponge iron, ores low in gangue, or specially produced pellets, are used. Otherwise, additional energy must be used to melt the gangue when melting sponge iron. The metallic iron/total iron ratio should, therefore, preferably be > 92 %. The carbon content of sponge iron from the gas reduction process is 1 – 2.5 %, which is higher than the typical value for sponge iron produced by the coal reduction process (0.1 – 0.2 %). A high carbon content can help to reduce the consumption of electrical energy for melting if the carbon is burned with air or oxygen to form carbon monoxide, which is post- combusted in the melting plant. New developments in direct reduction involve the production of iron carbide, which should give a carbon content of > 5 % of the DRI [27].

Table 9 gives typical figures for the composition of a Midrex sponge iron (gas reduction in a shaft furnace) and an SL/RN sponge iron (solid state reduction with coal in a rotary kiln). Table 10 gives typical figures for bulk density, lump density, and porosity of sponge iron produced from lump or pelletized ore, and for briquetted sponge iron [16].

Table 10. Properties of sponge iron [16]

Form	Bulk density, t/m^3	Lump density, g/cm^3	Porosity, %
Lumps	1.9	2 – 3.5	70 – 50
Pellets	1.7		
Briquettes	2.5	4.5 – 6	35 – 15

Figure 16. Required rate of addition of lime as a function of the silicon content of pig iron and iron content of slag [29]

When transporting and storing porous sponge iron, attention must be paid to its tendency to reoxidize exothermically, owing to the large surface: volume ratio. The heat given off can lead to ignition of the sponge iron and to a fire, e.g., during transport. This reoxidation behavior, typical of many types of sponge iron, can be characterized by determining the ignition temperature, the rusting behavior, and the evolution of hydrogen in a moist atmosphere. Safety precautions must always be taken for the transport, loading, unloading, and storage of sponge iron. Regulations and other information relevant to transport by sea have been published by insurance companies. The tendency to reoxidation can be reduced by passivation of the sponge iron. The best method of limiting transport hazards is briquetting.

3.1.4. Lime

Lime is used as a reagent and slag former in steel production. It is the main constituent of the most metallurgically effective slags that combine with the unwanted elements in the steel.

Lime (CaO) is formed on calcination of limestone ($CaCO_3$) at ca. 1000 °C. Depending on the calcination temperature, calcination time, dwell time in the furnace, and type of gas flow through the furnace, various qualities of CaO can be produced, e.g., soft- or hard-burned lime [28]. The quality requirements of the steel industry include high purity (94 – 97 % CaO), well-defined chemical composition, optimum grain size, and rapid dissolution in the slag. Calcined (soft-burned) dolomitic limestone is also used in steel production.

In steel production by top blowing with oxygen, the hot metal composition is of the greatest significance when determining the quantity of lime to be added for refining in the converter. The amount required to produce a slag that is slightly supersaturated with respect to lime is illustrated in Figure 16, which also shows the iron content of the slag [29]. As well as decreasing the silicon and sulfur content of hot metal, the changes brought about by the introduction of the combined blowing process in the mid-1980s had a further effect in reducing lime content [30], [31]. By bottom blowing with an inert gas to give agitation during oxygen blowing, the reactions approach equilibrium much more closely, and hence a better utilization of the slag is achieved. Figure 17 illustrates this trend toward a reduction in specific lime consumption, using German BOF steelmaking as an example. Between 1970 and 1990, specific lime addition was reduced from ca. 70 to ca. 45 kg per tonne of crude steel.

Figure 17. Variation in the specific consumption of lime and the silicon content of low-phosphorus pig iron in an oxygen steelmaking plant in the Federal Republic of Germany (1975 – 1990)

In electric steel production with scrap addition, the process in the 1970s was mainly to add an oxidizing slag, and then to change to a refining slag. Today, both low- and medium-alloyed steels are produced under one slag. The oxidizing treatment is followed by a reduction phase by the slag. All the other metallurgical operations have been moved to the later processing stages of the secondary metallurgy. Specific lime consumption in steel production in the electric arc furnace is 35 – 40 kg/t. Soft-burned lime usually has lump size 10 – 30 mm, and should have a sulfur content < 0.02 %. With sponge iron instead of scrap, the amount of slag increases, because of the silica introduced with the gangue materials in the sponge iron. The amount of lime added depends on the amount of SiO_2 that is to be reacted. The slag basicity (CaO/SiO_2) should be 1.5 – 2.

Modern developments in secondary metallurgy have led to new process steps in the operations that take place between the steelworks and the strand casting plant. Slags, which have become reactive contact phases, are now at the heart of metallurgical research and development. As there are many aims of secondary metallurgy, the slags used can differ widely. Lime-containing slags mostly consist of reactive $CaO - CaF_2 - Al_2O_3$ mixtures for steel treatment in the ladle furnace, for intensive blowing in the ladle, or as a basic covering slag. The compositions of desulfurizing slags are ca. 55 – 60 % CaO, 5 – 10 % CaF_2 and Al_2O_3. Typical lime addition rates are, therefore, 10 – 15 kg/t. As well as the intensive stirring process with synthetic slag, the injection of $CaO - CaF_2$ mixtures at the rate of 3 – 5 kg/t is common.

Metallurgical lime must fulfill special requirements for utilization of waste slag from the steelworks [32]. Steelworks slags, when used as hydratable components of building materials, should contain only such levels of lime and free magnesium oxide that volume stability can be absolutely guaranteed. For this reason, the relevant specifications limit the free lime content to < 7 wt % or < 4 wt %, according to the intended use (volume of intergranular free space).

The interests of the steelworks and the slag users coincide with respect to lime [32]. The steelworks require a readily soluble lime for metallurgical reasons. The slag user has problems with volume stability if the solid slag contains lime that failed to dissolve when it was liquid. Therefore, reactive, soft-burned lime should be used for slag utilization reasons.

3.2. Physical and Chemical Fundamentals

3.2.1. Thermodynamics

3.2.1.1. Metallic Systems Based on Iron

In steelmaking, the most common accompanying elements in molten iron are C, Si, Mn, P, S, and the gaseous elements H and N. In the reactions that take place when oxygen is brought into contact with the molten materials, the concentrations of the unwanted elements in the iron are reduced to the levels required in the steel produced. The thermodynamic data for metallic systems based on iron, such as solubility and activity, are of fundamental importance for the control of these reactions.

The state of carbon in Fe – C alloys can be seen from the phase diagram (Fig. 18) [33]. Carbon dissolves in both molten and solid iron. Its

solubility in the latter varies according to the crystal structure of the iron. Although carbon dissolves to only a very small extent in α-Fe and δ-Fe, its solubility in γ-Fe at 1153 °C is 2.1 %. The solid solution of γ-Fe – C is known as austenite. The solubility of carbon in molten iron is given by the equation [34], [35]:

$$[\%\mathrm{C}]_{\max} = 1.30 \times 2.57 \times 10^{-3} t$$
$$t = 1152 - 2000\,^{\circ}\mathrm{C} \tag{3.1}$$

The solubility of carbon in molten iron is also influenced by other elements present (Fig. 19) [34].

Figure 18. Phase diagram for Fe – C alloys

Figure 19. Effect of alloying elements on the solubility of carbon in molten iron alloys [34]

The effect of other elements on the activity of the carbon in molten iron can be represented by the interaction parameters $e_{\mathrm{C}}^{\mathrm{C}}$ and $e_{\mathrm{C}}^{\mathrm{X}}$. The value of $e_{\mathrm{C}}^{\mathrm{C}}$ at 1600 °C is 0.14 [36]. The activity of the carbon is only slightly dependent on temperature. The effect of other elements on the activity coefficient of carbon is shown in Figure 20 [36].

Figure 20. Effect of alloying elements on the activity coefficient of carbon in molten iron alloys [36]

The Fe – O phase diagram is shown in Figure 21 [37]. The liquid region, in which molten iron is in equilibrium with molten iron(II) oxide, is relevant to the steelmaking process. The solubility of oxygen in molten iron is limited by the precipitation of molten FeO in the reaction:

$$\mathrm{Fe\,(l) + O \longrightarrow FeO\,(l)}$$

The solubility of oxygen varies with temperature according to the equation [38]:

$$\log\,[\%\mathrm{O}]_{\max} = -\frac{6320}{T} + 2.734 \tag{3.2}$$

in the range 1530 – 1700 °C. Equation (3.2) corresponds to the line BB′ in Figure 21.

There have been many experimental determinations of oxygen activities in the system Fe – O and of the effect of othe elements X in the system Fe – O – X. The temperature dependence of $e_{\mathrm{O}}^{\mathrm{O}}$ is [36]:

$$e_{\mathrm{O}}^{\mathrm{O}} = -\frac{1750}{T} + 0.794 \tag{3.3}$$

The effect of various alloying elements and other additives on the activity coefficient $f_{\mathrm{O}}^{\mathrm{X}}$ at 1600 °C is shown in Figure 22 [39].

Hydrogen and nitrogen can have adverse effects on the properties of solid and liquid metals. During the process of steelmaking, hydrogen

from atmospheric moisture usually enters the steel. The most important source of nitrogen during steelmaking is atmospheric air. Nitrogen is also absorbed during oxygen blowing, the N_2 content of the O_2 used being ca. 3 %.

The solubility of H and N in iron obeys the Sievert square root law:

	T, °C	O_2, wt%	P_{CO_2}/P_{CO}
A	1536		
B	1528	0.16	0.209

[b] $P_{O_2} = 0.1$ MPa. [c] 5.75 kPa.

Figure 21. Phase diagram for Fe – O [37]

$$[\%\mathrm{H}] = K_{\mathrm{H}} \sqrt{p(\mathrm{H_2})} \tag{3.4}$$

$$[\%\mathrm{N}] = K_{\mathrm{N}} \sqrt{p(\mathrm{N_2})} \tag{3.5}$$

where p represents partial pressure.

The effect of temperature on solubility is reflected in variations of the equilibrium constants K_{H} and K_{N}. The solubility of hydrogen and nitrogen in pure iron at partial pressure 0.1 MPa (1 bar) is shown as a function of temperature in Figures 23 and 24 [40]. For hydrogen, the solution process is endothermic over the whole temperature range 400 – 1800 °C. Nitrogen dissolves exothermically in the γ-phase.

3.2.1.2. Slag Systems

In the steelmaking process, slags are formed as products of the refining reaction and by the addition of materials such as lime. It is extremely important that the slag forms quickly, enabling the important reactions between metal and slag, e.g., desulfurization and dephosphorization, to proceed until the required low levels of sulfur and phosphorus are obtained in the finished steel.

Calcium silicate slags are important in the metallurgy of steelmaking when the raw materials have a low phosphorus content. The essential system is $FeO - CaO - SiO_2$ (Fig. 29) [44]. In general, the total of these three components is $> 80\,\%$, the remainder consisting mainly of MnO, with smaller amounts of P_2O_5, MgO, Al_2O_3, and Cr_2O_3. Figure 29 shows the solid phases in equilibrium with the melt at various surfaces of the precipitate. Continuous lines separate the saturation surfaces of individual solid phases from each other, at which more than one phase is precipitated on cooling. The isotherms are shown as broken lines. For steelworks slags, the most important region includes the stability zones of the liquid slags, dicalcium silicate, tricalcium silicate, and lime. An important isothermal diagram for steel manufacture is that at 1600 °C (Fig. 30) [45], which shows lines of equal FeO activity for the equilibrium with metallic iron. In the area a – b – c – d – e – f, the slags are liquid at 1600 °C. All other areas consist of more than two phases. The activity of FeO gives a measure of the tendency of the slag to oxidize, and from it the corresponding oxygen content of the melt can be deduced. The FeO activity is also important in desulfurization and dephosphorization.

3.2.1.3. Metal – Slag Reactions

3.2.1.3.1. Refining Reactions

In the refining treatment of molten pig iron to make steel, carbon is removed along with other elements, e.g., Si and Mn, by blowing the molten metal with oxygen. The thermodynamics of the reactions are independent of the process used; differences between the various processes affect only the kinetics of the individual reactions. Typical concentration changes in the steel melt during oxygen blowing in a basic oxygen converter are shown in Figure 31 [46]. The main aim is to reduce the carbon content to the desired value in the shortest possible time. However, the time must be long enough to enable the slag to form, the desired tapping temperature to be achieved, and phosphorus and sulfur to be removed from the system until the desired levels are reached.

Decarburization is achieved by the reaction:

$$C + O \rightleftharpoons CO \tag{3.6}$$

The CO bubbles promote homogenization of the melt, and the elements H and N dissolved in the melt are picked up in the bubbles as they ascend. The equilibrium constant of the decarburization reaction [47] is given by:

$$\log K = \frac{1160}{T} + 2.003 \tag{3.7}$$

In practical decarburization processes, a simplified expression for the equilibrium between C and O is used

$$[\,\%C]\,[\,\%O] = 0.0025\,p\,(CO) \tag{3.8}$$

at 1600 °C.

Silicon is rapidly removed during the oxidation process, owing to its high affinity for oxygen, and combines with the lime in the slag; oxidation takes place by the reaction:

Figure 29. Phase diagram for CaO – FeO – SiO_2 [44]

Figure 30. Phase diagram for CaO – FeO – SiO_2 with lines of equal activity for FeO at 1600 °C [45]

$$Si + 2\,O \rightleftharpoons SiO_2 \tag{3.9}$$

The equilibrium constant for this reaction is:

$$\log K = \log \frac{a_{SiO_2}}{a_{Si}\,a_O^2} = \frac{30110}{T} - 11.4 \tag{3.10}$$

The exothermic oxidation of silicon provides a large proportion of the process heat. The oxidation product SiO_2, together with FeO, forms the first slag. This reduces the melting point of the added lime to such an extent that a reactive liquid slag can be formed. Therefore, the amount of CaO added and the amount of slag formed are mainly determined by the Si content.

Manganese is removed at the beginning of the oxidation process, mostly in parallel with silicon. Oxidation of manganese can be represented by the equation:

$$[Mn] + [O] \rightleftharpoons (MnO) \tag{3.11}$$

The equilibrium constant is given by

$$\log K = \log \frac{a_{\mathrm{MnO}}}{a_{\mathrm{O}} a_{\mathrm{Mn}}} = \frac{12590}{T} - 5.53 \qquad (3.12)$$

Toward the end of the silicon oxidation, the increased melt temperature leads to the reduction by carbon of the manganese oxide in the slag, according to the equation:

$$(\mathrm{MnO}) + [\mathrm{C}] \rightleftharpoons [\mathrm{Mn}] + \mathrm{CO} \qquad (3.13)$$

However, at the end of the blow, the manganese content decreases continuously, owing to oxidation of the manganese, mainly by FeO in the slag:

$$(\mathrm{FeO}) + [\mathrm{Mn}] \rightleftharpoons (\mathrm{MnO}) + \mathrm{Fe(l)} \qquad (3.14)$$

Figure 31. Changes in melt composition during the blow in a basic oxygen steelmaking converter (idealized) [46]

3.2.1.3.2. Dephosphorization

The conditions in steelmaking processes favor dephosphorization of iron, which takes place by oxidation of phosphorus and combination with a basic slag. The reaction proceeds as follows:

$$2\,[\mathrm{P}] + 5\,[\mathrm{O}] + 4\,(\mathrm{CaO}) \rightleftharpoons (4\,\mathrm{CaO} \cdot \mathrm{P_2O_5}) \qquad (3.15)$$

The equilibrium constant is given by:

$$\log K = \log \frac{a_{4\mathrm{CaO}\cdot\mathrm{P_2O_5}}}{a^4_{\mathrm{CaO}}\, a^2_{[\mathrm{P}]}\, a^5_{[\mathrm{O}]}} = \frac{61100}{T} - 23.3 \qquad (3.16)$$

This expression shows that the conditions for oxidative dephosphorization are: (1) oxidizing slag (high FeO activity); (2) high activity of lime in the slag; and (3) low temperature, as reaction (3.15) is exothermic. These conditions are particularly well satisfied at the start of the process.

In low-phosphorus pig iron, the type most commonly produced today, the slag formed during steelmaking consists mainly of CaO, SiO_2, and FeO_n, with P_2O_5 content ca. 1 – 2 %. The phosphorus equilibrium in this type of slag has been thoroughly investigated. In Figure 32, lines of equal phosphorus distribution at 1600 °C are shown for the system $\mathrm{CaO} - (\mathrm{SiO_2} + \mathrm{P_2O_5}) - (\mathrm{FeO}_n + \mathrm{MnO})$, with 6 % MnO and 2 % MgO. As expected, the lines are approximately parallel to the lime saturation line.

Figure 32. Lines of equal phosphorus distribution in the system $\mathrm{CaO} - (\mathrm{SiO_2} + \mathrm{P_2O_5}) - (\mathrm{FeO}_n + \mathrm{MnO})$ [48]

3.2.1.3.3. Desulfurization

Unlike dephosphorization, desulfurization is a reduction reaction. Since the oxidizing conditions in the converter do not favor the removal of sulfur from the melt, desulfurization is mainly carried out by treatment of the pig iron or of the metal in the ladle.

Desulfurization can be carried out by means of the precipitation reaction that occurs when elements with a high affinity for sulfur are added, either by taking up the sulfur into the slag phase, or by transferring it into the gas phase.

The affinity for sulfur of a desulfurizing agent is indicated by the solubility product of its sulfide in molten iron (Fig. 33) [49], the most stable of these being calcium sulfide. Although the alkaline earths and rare earths form relatively stable sulfides, their oxides are much more stable; the sulfides are formed only if the dissolved oxygen has been removed. The most commonly used desulfurizing agents are added to the steel in the form of alloys (CaSi, CaC_2, CaAl, etc.), by

special techniques. The desulfurization reaction can be represented by the typical equation:

Figure 33. Equilibria between sulfur and various metallic elements in molten iron [49]

$$CaC_2(s) + [S] \longrightarrow CaS(s) + 2\,[C]$$

for which

$$\Delta G^\circ = -359\,000 + 109.4\,T\ \mathrm{J/mol} \tag{3.17}$$

Desulfurization by slag treatment is represented by the following equation, according to the ionic theory for slags:

$$(O^{2-}) + [S] \rightarrow (S^{2-}) + 2\,[O]$$

$$\Delta G^\circ = 71965 - 38\,T\ \mathrm{J/mol} \tag{3.18}$$

The most favorable thermodynamic conditions for slag desulfurization are: (1) high basicity of the slag; (2) low oxygen content in the slag or melt; and (3) high temperature.

Figure 34 shows the partition of sulfur between aluminum-containing steel and $CaO - Al_2O_3 - SiO_2 - MnO$ slag containing 5 % MgO at 1625 °C [50]. Slags of this type are used for the desulfurization of steel in ladle metallurgy.

Figure 34. Sulfur partition coefficient L_S between aluminum-containing steel ($a_{Al} = 0.07\,\%$) and $CaO - Al_2O_3 - SiO_2 - MgO$ slags containing 5 % MgO at 1625 °C [50]

The sulfur in pig iron can also be removed by Na_2CO_3. The desulfurization reaction is:

$$Na_2CO_3 + [S] + 2\,[C] \longrightarrow (Na_2S) + 3\,CO(g) \tag{3.19}$$

or

$$Na_2CO_3 + [S] + [Si] \longrightarrow (Na_2S) + CO(g) + (SiO_2) \tag{3.20}$$

The Na_2S formed can be oxidized by air:

$$2\,(Na_2S) + 2\,O_2(g) \longrightarrow 2\,SO_2(g) + 2\,(Na_2O) \tag{3.21}$$

3.2.1.3.4. Deoxidation

At the end of the refining process, there is a considerable amount of oxygen dissolved in the molten steel; this can be removed by adding elements with a sufficient affinity for oxygen (precipitation deoxidation), or by slags which take up an amount of oxygen from the melt corresponding approximately to the equilibrium distribution (diffusion deoxidation).

The reaction between oxygen and a metal M in precipitation deoxidation can be represented by the equation:

$$x\,[M] + y\,[O] \longrightarrow (M_xO_y) \tag{3.22}$$

The equilibrium constant is:

$$K = \frac{a_{M_xO_y}}{a_M^x\, a_O^y} \tag{3.23}$$

In practice, either the deoxidation constant $K' = a_M^x\, a_O^y$ or the solubility product $K'' = [\,\%M]^x\,[\,\%O]^y$ is usually used. Small values of K' or K'' correspond to high deoxidizing power.

The relative deoxidizing powers of various elements are shown in Figure 35 [51]. The activities, or concentrations, of oxygen are plotted against those of the deoxidation elements on a logarithmic scale. The three deoxidation elements most commonly used, in increasing order of effectiveness, are Mn < Si < Al. Aluminum is one of the most powerful deoxidation elements.

Figure 35. Deoxidation equilibria in molten iron at 1600 °C [51]

Figure 36. Deoxidation diagram for Al – Si – O at 1600 °C [49]

Deoxidation elements are often used in combination; the advantage of this lies partly in lowering the thermodynamic activity of the oxides formed, owing to compound formation, or dilution in the slag, and partly in the formation of oxidic slags with lower melting points, which separate more readily from the steel melt, or can be shaped at the rolling temperature. Figure 36 is a graphical representation of deoxidation with Al – Si. Various deoxidation products (alumina, mullite, and silicate) are formed, depending on the $[a_{Al}]/[a_{Si}]$ ratio.

In diffusion deoxidation, no inclusions are formed in the melt, but longer reaction times are necessary to remove the oxygen. The reaction can be represented by:

$$[O] + Fe(l) \longrightarrow (FeO) \tag{3.24}$$

Decreasing the FeO content of the slag leads to removal of oxygen from the melt. Diffusion deoxidation is being replaced by precipitation deoxidation.

3.2.1.4. Metal – Gas Reactions

If there is no slag on the surface of the molten metal, or if gas bubbles are formed within the melt, metallurgical reactions between the metal and gas phases take place. These include decarburization and degassing, either under reduced pressure, or by bubbling an inert gas such as argon through the melt.

As mentioned in Section 3.2.1.1, the concentrations of the gases dissolved in the iron depend on their partial pressures (Fig. 37). Pressure reduction can cause hydrogen and nitrogen to be removed from the melt, but this is not the case with oxygen. Although the solubility of oxygen varies with pressure according to the equation:

$$[\%O] = K_O \sqrt{p(O_2)}$$

it is not feasible to remove oxygen simply by pressure reduction, as the required oxygen partial pressure is less than that attainable in vacuum vessels (10 Pa). However, it is possible to use vacuum in conjunction with reaction (3.6) in the melt between carbon and oxygen to form the gaseous deoxidation product CO. The equilibrium constant:

$$K = \frac{p(CO)}{a_C a_O}$$

explains the strong pressure dependence. Figure 38 shows the equilibrium between oxygen and carbon as a function of p(CO) [52]. A decrease in p(CO) leads to simultaneous decarburization and deoxidation.

Figure 37. Solubility of nitrogen and hydrogen in molten iron [40]

Figure 38. Equilibria between carbon and oxygen dissolved in molten iron with CO and CO_2 at various pressures and 1600 °C [52]

Figure 39. Schematic concentration profiles across a phase boundary

Dissolved hydrogen and nitrogen can also be removed without vacuum degassing by bubbling an inert gas through the melt. As the partial pressures of the hydrogen and nitrogen in the bubbles of inert gas are almost zero, hydrogen and nitrogen diffuse from the melt into the bubbles, owing to the concentration difference, and ascend with them.

3.2.2. Kinetics and Mass Transfer

3.2.2.1. Kinetics of Heterogeneous Reactions

In the metallurgy of steel production, the kinetics of the heterogeneous reactions are of interest because the individual homogeneous phases are usually in local thermodynamic equilibrium, so that macroscopics reactions do not occur. Heterogeneous reactions occur between the various phases that are not in thermodynamic equilibrium with each other. Figure 39 shows the concentration profile of a substance in two phases in contact with each other. The total reaction is made up of several steps:

1) Transport of the reactants to the phase boundary
2) Chemical reaction at the phase boundary
3) Transport of the reaction products from the phase boundary

The overall rate depends on the rate of the slowest step, known as the rate-determining step. If the overall process is considered, the mass flux density j is:

$$j = \left(C^{\mathrm{I}} - \frac{C^{\mathrm{II}}}{K}\right) / \left(\frac{\mathrm{I}}{\beta_{\mathrm{I}}} + \frac{\mathrm{I}}{k} + \frac{\mathrm{I}}{K\beta_{\mathrm{II}}}\right) \tag{3.25}$$

where C^{I}, C^{II} are concentrations in phases I and II, K is the equilibrium constant of the heterogeneous reaction, β_{I}, β_{II} are mass transfer coefficients, and k is the reaction rate constant. The equation:

$$\frac{\mathrm{I}}{\beta_{\mathrm{tot}}} = \frac{\mathrm{I}}{\beta_{\mathrm{I}}} + \frac{\mathrm{I}}{k} + \frac{\mathrm{I}}{K\beta_{\mathrm{II}}} \tag{3.26}$$

defines the overall mass transfer coefficient β_{tot}. Therefore, from Equation (3.25):

$$j = \beta_{\mathrm{tot}} \left(C^{\mathrm{I}} - \frac{C^{\mathrm{II}}}{K}\right) \tag{3.27}$$

The mass transfer coefficients β_{I} and β_{II} are obtained from theory of mass transfer by using experimental data. The rate constant k is obtained

from the chemical kinetics of phase boundary reactions for metallurgical systems. These rate constants are usually greater than the mass transfer coefficients of the transport processes that take place before and after the chemical reactions. The overall rate is therefore determined by mass transfer.

Equation (3.27) gives the rate of mass transfer to a phase boundary when the mass transfer coefficient is known. To obtain an expression for the variation with time of the concentration of a dissolved substance in the mother phase, a mass balance must be carried out which takes account of the nature of the phase contact and the characteristic parameters for emulsified systems [53].

3.2.2.2. Flow and Mass Transfer Coefficients

Mass transfer into a phase is made up of diffusion and convection. In the interior of the phase, sufficient flow takes place to give a uniform concentration. Concentration gradients exist only near the phase boundary. As there is no flow at this boundary layer, mass transport takes place by diffusion, and Fick's first law applies:

$$j = D\frac{C^{\mathrm{I}} - C^{\mathrm{I}*}}{\delta_{\mathrm{N}}} \tag{3.28}$$

where the asterisk indicates the phase boundary.

If this is combined with the flow equation $j = \beta(C^{\mathrm{I}} - C^{\mathrm{I}}*)$, the equation $\beta = D/\delta_{\mathrm{N}}$ is obtained. Here, δ_{N} denotes the thickness of the boundary layer, and D the diffusion coefficient of the overlying material. To determine β, it is necessary to determine the boundary layer thickness, whose value depends on flow conditions. Theoretical analysis and experimental investigation of the various flow fields that occur in metallurgical processes yield a formula for calculating the mass transfer coefficient in dimensionless form.

3.2.2.2.1. Metal – Glas Phase Boundaries with Nonturbulent Flow

The flow field is represented in Figure 40. The flow from the interior of the melt is first deflected at a stagnation point, e.g., the top of a column of bubbles or the middle of an inductively agitated melt, flows parallel to the upper surface, and is again deflected at a later stagnation point, e.g., the wall, and flows back into the interior. In this way, the surface is continuously renewed. The diffusion process takes place between the gas phase and the metal flowing to the surface. A mean mass transfer coefficient for this condition can be calculated in the form of a Sherwood number Sh, as a function of the Reynolds number Re and the Schmidt number Sc:

$$Sh = \frac{2}{\sqrt{\pi}} Re^{1/2} Sc^{1/2} \tag{3.29}$$

Where $Sh = \frac{\beta l}{D}$, $Re = \frac{ul}{\nu}$, $Sc = \frac{\nu}{D}$; β is the mean mass transfer coefficient (cm/s), l the flow length (cm), u the flow rate (cm/s), ν the kinematic viscosity of the melt (cm^2/s), and D the diffusion coefficient of the overlying material (cm^2/s).

Figure 40. Mass transfer with continuous renewal of the free surface (schematic)

Figure 41. Flow field at a liquid – liquid phase boundary

3.2.2.2.2. Metal – Slag Phase Boundaries with Nonturbulent Flow

This flow field is represented in Figure 41. Friction takes place between the slag and the metal. The phase boundary moves at a velocity u_{i} during mass transfer. In the determination of the mass transfer, momentum transfer

due to friction must be taken into account. Equations for the flow film thicknesses on the metal and slag sides are first obtained. By including the condition that the shearing forces on each side of the phase boundary must be equal, the velocity of the phase boundary obtained and the mass transfer calculated.

3.2.2.2.3. Solid (Metal or Slag) – Liquid Phase Boundaries with Nonturbulent Flow

This condition represents, e.g., the processes of dissolution of alloys, or the solution abrasion of refractory materials. Mass transfer takes place on the liquid side. As shown in Figure 42, the flow rate, which is u_∞ within the melt, falls to zero at the boundary layer, and both the flow boundary layer and the diffusion boundary layer must be considered on the side of the melt. The mass transfer coefficient can be obtained by theoretical calculations from the equation:

$$Sh = 0.664 Re^{1/2} Sc^{1/3} \tag{3.30}$$

Figure 42. Mass transfer at a wall

3.2.2.2.4. Mass Transfer with Turbulent Flow

In metallurgical vessels, turbulent flow is usually present, caused by ascending CO bubbles and/or blowing with oxygen. In turbulent flow, turbulence spheres at the phase boundary contribute additional mass transfer by their flow components perpendicular to the phase boundary. This mass transfer can be regarded as turbulent diffusion, leading to an increased value of the diffusion coefficient. To calculate the mass transfer at a solid wall with turbulent flow, the following equation can be used [54]:

$$Sh = 0.037 Re^{0.8} Sc^{0.2} \tag{3.31}$$

At free surfaces [53], [54]:

$$Sh = 0.32 \left(\frac{D \varrho u_\tau^3}{\sigma_{\text{equiv}}} \right)^{1/2} \tag{3.32}$$

where D is the diffusion coefficient, ϱ the density of the melt, σ_{equiv} the equivalent interfacial tension of the melt, and u_τ the shearing force rate for turbulent flow.

The equivalent interfacial tension differs from the normal interfacial tension in that the back pressure, caused by the irregularity of the boundary surface, is expressed as the sum of the effects of interfacial and gravitational forces [54]. For steel melts, which have high interfacial tensions, σ_{equiv} can be assumed equal to the interfacial tension of the melt. The shearing force rate u_τ is a measure of the degree of turbulence. The value must be determined by turbulence measurements. For steel melts, this can at present only be investigated with the aid of mathematical models.

Equation (3.32) is also valid for metal – slag phase boundaries with turbulent flow, if there is no turbulence in the slags, and if the full weight of the stationary slag layer on the melt is considered when calculating the equivalent interfacial tension. If there is any turbulence in the slag, this should be included. However, it is often negligible.

3.3. Production Processes

Steel production depends on the availability of raw materials such as pig iron, scrap, and sponge iron. There are two fundamentally different methods (Fig. 43) [55]: blowing oxygen into liquid iron (mainly pig iron), and smelting iron-containing materials, such as scrap and sponge iron.

A typical example of the first method is the oxygen converter. In the electric furnace, and (now of less importance) the open hearth furnace, large amounts of scrap and sponge iron can be melted together. Depending on local conditions, mixed methods can also be used, in which various proportions of scrap

Figure 43. Crude steel production methods

and pig iron are processed, e.g., the KMS (Klöckner – Maxhütte – Stahlerzeugungsverfahren) and EOF (energy-optimized furnace) processes.

The object of all steel production processes is the removal of unwanted metallic, nonmetallic, and gas-forming elements from the raw materials, and the controlled addition of alloying elements to obtain the required characteristics of the various grades of steel.

The growth of world crude steel production, and the proportional contributions of the various processes are shown in Figures 44 and 45 [56], [57].

Figure 44. Growth of world pig iron and crude steel production by various processes

Figure 45. Growth of crude steel production, with contributions of the various production processes
∗ Estimated.

3.3.1. Oxygen-Blowing Processes

Unwanted elements in pig iron (and sometimes in scrap), principally carbon, silicon, and phosphorus, are removed by the oxidation reactions

described in Section 3.2, and transferred into the gas or slag phases (decarburization).

Figure 46. Section through a Thomas converter after 400 melts

The carbon monoxide produced is a source of thermal energy. After thorough purification, it is collected in gasholders and burned to provide heat for associated production plant. The oxides SiO_2 and P_2O_5 dissolve in the liquid slags formed from the added lime and the iron oxide produced during the oxidative decarburization processes.

The energy required to raise the temperature and melt the raw materials during the blowing process comes from the enthalpies of the oxidation reactions:

$$2\,C + O_2 \longrightarrow 2\,CO \quad \Delta H = -221\,kJ$$

$$2\,Fe + O_2 \longrightarrow 2\,FeO \quad \Delta H = -529\,kJ$$

$$Si + O_2 \longrightarrow SiO_2 \quad \Delta H = -878\,kJ$$

$$2\,Mn + O_2 \longrightarrow 2\,MnO \quad \Delta H = -771\,kJ$$

From ca. 1870, conversion of pig iron to liquid crude steel was carried out by blowing air, the oxidizing agent, through tuyeres in the base of a bottom-blown converter (tiltable steel vessel with refractory lining) containing a 20 – 80 t charge. Steel production processes using air blowing can be subdivided into the Bessemer process (only for low-phosphorus pig iron) and the Thomas process (capable of removing phosphorus). In the Bessemer process, the converter was lined with silica bricks. It was not possible to use a lime-containing slag to combine with the P_2O_5, owing to the acidic lining. In the Thomas process (Fig. 46), dolomite was used to line the converter, and a lime-based slag could then be used to treat phosphorus-containing pig iron [58].

The nitrogen in air dissolved to some extent in the liquid steel, and has a detrimental effect on its properties. Increasing quality requirements (aging stability, etc.) and the unfavorable economics of this process led to its discontinuation.

3.3.1.1. LD and OBM Processes

The first LD (Linz-Donawitz) converter, with a capacity of 30 t, was operated in Linz in 1952. The decarburization reaction is greatly speeded up by the use of pure oxygen, giving blowing times of 10 – 20 min. The oxidation enthalpies result in lower heat losses and enable more scrap or ore to be added. The converters have total charge 50 – 400 t, and are lined with dolomite or magnesite bricks [55].

Oxygen is injected from above through a water-cooled lance with several nozzles, onto the surface of the melt (Fig. 47). The high-pressure jets of oxygen (up to 1.2 MPa) oxidize the iron, carbon, and other elements at rates depending on their affinity for oxygen. The gas reactions cause thorough mixing of the molten materials, and this is maintained after completion of the blowing process by purging bricks built into the base of the vessel. Temperatures of 2500 –3000 °C are produced in the central reaction zone, and a reactive slag is rapidly formed from the added lime and the oxidized iron. The thermodynamic and kinetic processes are described in Sections 3.2.1 and 3.2.2. The heat and mass transfer processes take place according to the rules given in Section 3.2.2.

Figure 47. Top-blown oxygen converter

Figure 48. Section through an OBM converter
Oxygen is injected from below, through tuyeres cooled by hydrocarbons blown into the melt

The OBM (oxygen-blowing technique) (Fig. 48), a modification of the air blast processes, was developed in 1968 – 1969 in Sulzbach-Rosenberg [55]. Pure oxygen is passed through bottom tuyeres into the melt. These tuyeres are highly stressed, and are stabilized by cooling them with hydrocarbons. The cooling effect is a result of the endothermic decomposition of the hydrocarbons by the hot melt. The OBM process causes more intensive mixing of the steel and the slag compared with the method of blowing in the oxygen from above. This gives improved reaction kinetics and yield, owing to the lower iron content of the slag. The advantages of the more rapid slag formation and the less violent blow can be enhanced by adding powdered lime through the bottom of the converter, along with the oxygen. However, the capacity of the OBM process for melting scrap is limited in comparison with the LD process, owing to the lesser extent of afterburning of the waste gases, and the smaller amount of iron oxidation.

The combined blowing technique in general use today (Fig. 49) has been developed from the top-blowing process and past experience of the bottom-blowing process [55]. The combined process provides:

1) Homogeneous melts due to rapid breakdown of the scrap
2) Reduction of the blowing cycle time by 25 %
3) Higher yield of iron and alloying elements
4) Better control of the chemical composition
5) Improved purity
6) Lower quantity of slag and reduced tendency for it to be ejected
7) Increased lifetime of the converter lining
8) More favorable conditions for the measuring systems for process control

Figure 49. Combined blowing technique with top-blowing lance or side tuyere

Plant layouts do not differ greatly from one another. Figure 50 shows a side view of the converters and continuous casting plant of a steelworks [55].

Depending on the products required, the pig iron in the torpedo ladle car or filling pit is desulfurized by blowing with slag formers containing lime and/or magnesium. In Japan, for steel products with a very low phosphorus content, it is also usual to remove the silicon and phosphorus

[59]. In this case, the converter simply removes carbon from the melt (Fig. 51).

Figure 51. Hot metal pretreatment process at Mizushima works

The mathematical model of the process calculates the quantities of pig iron, scrap, and lime for the melt (based on the composition and temperature of the raw materials); the nominal tapping temperature; and the analysis of the crude steel, and starts the oxygen addition after the scrap and pig iron have been charged. Distribution of the oxygen and control of the height of the lance are computer controlled. The course of the blowing operation is set by the dynamic process control, which requires occasional fine adjustments based on "sub-lance measurements", that give the temperature and the carbon and oxygen content of the melt. Other elements may also be determined if required. Figure 52 shows how the melt temperature and composition change during the blowing operation. Here, the final composition is 0.059 % C, 0.031 % Mn, 0.018 % P, 0.019 % S, 0.003 % N, and 0.083 % O. Figure 53 shows the corresponding changes in the composition of the slag [60].

Figure 52. Changes in melt temperature and composition during blowing

Figure 53. Changes in slag composition during blowing

At the end of the oxygen treatment, the converter is tilted and the steel is tapped into a ladle (a steel container with bottom-pouring facility and refractory lining). The steel is separated from the slag during emptying of the converter by means of a floating stopper introduced into the tapping spout. This prevents the slag, which is of lower density, from running out. Alternatively, an electromagnetic measurement in the tapping system can give a signal for the emptying process to be stopped.

To prevent emission of dust in the waste gases, all sources of dust, such as the pig iron handling and charging operations, lime feeding equipment, etc., are linked to a filtering system, usually cloth filters. The physical and chemical heat of the converter waste gases are utilized by installing a waste heat steam boiler with associated electrostatic filter or scrubber. The waste gases, at 1400 – 1600 °C, supply heat to the steam generation system, and the cooled gases, calorific value ca. 7000 kJ/m^3, are collected in a gasholder after purification. The dust collected in the filters or scrubbers can be recycled to the process, after suitable treatment.

3.3.1.2. Other Developments

Steel production processes based on an air or oxygen blast are autothermic, i.e., the energy requirement is provided by the physical and chemical heat from the pig iron. The use of scrap is limited by the composition and temperature of the pig iron, and varies between 0 and 20 %, depending on process variations and quality requirements.

Higher additions of scrap require the use of an allothermic process, with added fuel. In the KMS (Klöckner – Maxhütte – Steelmaking Process) process, additional energy is provided by adding hydrocarbons during scrap preheating, or powdered coal or coke during the blowing operation. This process is extremely flexible with regard to the metallic materials used, i.e., scrap, pig iron, and sponge iron.

In the KS process, the use of pig iron is completely eliminated. In the first phase, a carbon-rich melt is produced by melting scrap and adding carbon by a blowing process, together with an equivalent amount of oxygen. Heat transfer is optimized by afterburning the reaction gases. In the secound phase, conversion of the carbon-rich melt to steel is completed by the further addition of scrap.

In the Tula process (developed in the former Soviet Union), a carbon- containing material in lump form is added from above to a combined blowing converter. This provides the energy required for melting the scrap.

The EOF furnace (energy-optimized furnace) uses combustion of the waste gas and continuous preheating of the scrap in the hot waste gas stream to minimize the additional fuel requirements for an increased proportion of scrap in the melt. This has enabled up to 60 % steel scrap to be used.

3.3.2. Electric Steel Process

In the electric steel process, the heat required is obtained not by oxygen combustion of the accompanying elements in the pig iron, but from electrical energy. The conversion of electrical energy into heat can be achieved by an electric arc, induction, or plasma furnace. Electric steel processes are based on the use of scrap, with small amounts of solid pig iron. For a long time, the use of these processes was limited to the production of special steels, as energy consumption was high and the economics were unfavorable. Increases in the size of power stations and the capacity of electrical distribution systems have enabled batch weights to be increased, and the costs of energy, electrodes, refractory material, and capital investment to be reduced. Today, this process is second in importance only to the oxygen-blowing process in world crude steel production (see Fig. 47).

Over 90 % of all electric steel produced is by the use of the a.c. electric arc furnace [61]. Three

graphite electrodes carry the current through the furnace roof into the charge of metal. The electric arc formed melts the charge at temperatures up to 3500 °C. The furnace has the following essential components: the vessel or shell with a furnace door and a tapping hole; the roof which can be removed for charging; electrode arms which support the electrodes; tilting equipment for emptying the furnace; the furnace transformer; and the measuring and control equipment.

The melting procedure for the electric arc furnace comprises the following stages:

1) Charging
2) Melting
3) Oxidization (decarburization), with an increase in temperature
4) Tapping

The raw materials (scrap, sponge iron, pig iron, alloying elements, etc.) together with the required additives (lime, coal, ore, etc.) are loaded into special charging buckets which are then emptied into the furnace through a bottom opening. To fill the furnace, two or three charging operations are required, between which the scrap is partially melted.

The melting process begins with switching on the current and striking the arc. A supplementary blow with oxygen and fuel – oxygen mixtures accelerates melting and reduces current consumption. The duration of the melting period is determined by the electric power limit and the maximum heat load of the furnace shell.

Oxidation of elements, such as silicon, manganese, carbon, phosphorus, and sulfur begins during the melting phase as the liquid reactants, steel and slag, react with the added oxygen. The gaseous carbon monoxide formed from the reaction between the iron oxide and the carbon causes bubbling in the melt and purges the hydrogen and nitrogen. Removal of the phosphorus as calcium phosphate in the slag during the oxidation phase is important, and all the other metallurgical processes take place during the reductive secondary metallurgical treatment in the ladle or ladle furnace.

After the steel has reached the required temperature, the tap hole is opened and the furnace is tilted to empty it into the ladle below.

The development of the modern electric steel process began early in 1960, using powerful transformers and blowing with oxygen (Fig. 54) [62]. Modern furnace design and process control techniques have made it possible to increase the specific transformer power from 300 – 400 kVA/t to 800 – 1000 kVA/t. The electric furnaces of this new generation are operated at a power factor of 0.8 – 0.86, and enable tap-to-tap times of 50 – 80 min, and throughputs of > 100 t/h to be achieved (Fig. 55).

Figure 54. Development of specific installed power

Figure 55. Effects of developments in electric arc furnace technology since 1965 on specific power and electrode consumption

The essential characteristics of modern electric steel production are:

1) Process automation

2) Enclosure of the furnace
3) Preheating of the scrap
4) Water- cooled wall and roof elements
5) Gas/oil – oxygen jet burners
6) Foam slagging
7) Current- carrying supporting arms for the electrodes
8) Electrode cooling
9) Facilities for charging through the furnace roof
10) Bottom stirring devices
11) Slag-free tapping (eccentric bottom tap hole)

Owing to their high energy input, modern electric furnaces produce considerable quantities of smoke and waste gas. To minimize environmental pollution, the furnaces are enclosed. Conditions in the workplace and surroundings can thus be maintained to a standard that meets legal requirements.

Figure 56. Direct current arc furnace
The bottom is made of electrically conducting refractory material to ensure reliable and durable continuity

The waste gases produced in the furnace are extracted through an aperture in the furnace roof, and the dust from various sources in the furnace area is collected in the upper part of the housing. This is constructed from sound-insulating elements, and reduces the noise level from the furnace to 20 – 25 dB. The waste gas is passed through a cooler which can also serve to recover the heat, and is then dedusted by cloth filters. In some operating conditions, the dust from the electric furnace can contain considerable quantities of heavy metals, such as zinc and lead, and so it is worth recovering them.

The slags produced consist of calcium silicate with 10 – 15 % iron oxide. These are quite stable, and can be used as fill for road and dam construction.

The very rapid development of the d.c. electric arc furnace began in the middle of 1985 (Fig. 56) [63]. Important advantages are:

1) Lower electrode consumption
2) Savings in electrical energy
3) Smaller effect on the electricity supply system
4) Symmetrical distribution of heating in the melt
5) Stirring effect on the melt

The central electrode becomes the cathode, and the melt the anode, the bottom of the furnace vessel being insulated from the wall. Current-carrying elements are built into the hearth, and provide an electrial connection to the melt.

The d.c. arc acts as a jet pump, directing the gases in and around the electric arc plasma toward the melt, causing efficient heat transfer from the electrode to the melt. The largest d.c. furnace operating has a capacity of 130 t, with a transformer power of 100 MV · A, and a steel output of 10^6 t/a.

An important feature of modern electric steel production is computer control. The supervision and control of the production units, combined with precise data collection, leads to improved material flow and more efficient utilization of energy and alloying metals, and ensures high and reproducible quality.

3.3.2.1. Special Processes

In foundries, induction furnaces are widely used for melting and holding steel and nonferrous alloys [63]. The water- cooled, current-carrying coil surrounds a refractory-lined crucible (Fig. 57) that holds the material to be melted. Electricity is supplied by a medium-frequency (MF) frequency converter, fed from a high- or low-voltage transformer. The current density can be 1 MW/t, and an output of 15 t/h can be obtained from an MF furnace with a capacity of 8 t.

Since the development of high-power plasma burners, it has become possible to use plasma melting furnaces for the production of special steels in 40 t batches. The energy is supplied by adjustable d.c. argon plasma burners, built into

Figure 57. Electric induction furnace
a) Circuit breaker; b) Transformer; c) Frequency converter; d) Capacitor bank; e) Induction furnaceMelting capacities of 15 t/h can be achieved at current densities of 1 MW/t in an 8 t medium-frequency furnace

the furnace shell. The burner produces a plasma (ionized gas) in the electric arc, at temperatures 3000 – 5000 °C, and this melts the furnace contents. The use of inert gases for the plasma protects the melt against reactions with oxygen, nitrogen, hydrogen, etc., thereby ensuring a high yield of alloy. Carburization of the melt does not occur, as there are no graphite electrodes. Vacuum treatment of the steel is not necessary.

For the production of special alloys containing high proportions of alloying elements with a high affinity for oxygen (Al, Ti, etc.), it is common to use inductively heated or electron beam vacuum furnaces.

3.3.2.2. The Siemens – Martin Open Hearth Process

In 1960, the Siemens – Martin open hearth process (Fig. 58) produced ca. 70 % of the world's crude steel, but this rapidly declined following the growth of the oxygen-blowing and electric steel processes, and ceased operation after a few years.

Figure 58. German – American design for a 250 t furnace for gas and oil firing [64]

It was developed for melting scrap, and was characterized by its great flexibility with respect to the proportions of pig iron and scrap used. The tank-shaped furnaces are heated by fossil fuels such as gas or oil, burned in hot air. The regenerative air preheating invented by Siemens takes place in "checker chambers" that contain refractory bricks heated by the waste gas, and are situated under the furnace. The combustion temperatures achieved enable steel scrap to be melted.

Figure 59. The Fe – C – Cr – O system

The capacity of these furnaces is 50 – 1000 t. The use of air for the combustion leads to the production of large quantities of waste gas, whose purification, sometimes including desulfurization, is difficult and expensive. Additional oxygen, introduced through lances or burners (tandem furnaces), has been used to improve operation, but this leads to severe erosion of the refractory furnace lining. The open hearth process

has in general lost its importance, as it cannot achieve either the output or flexibility of blowing processes.

Figure 60. Free energy of oxidation of Cr, P, and C as a function of temperature

3.3.3. Production of Stainless Steels

Although world steel production is subject to very severe fluctuations dictated by market conditions, the average growth rate of stainless steels (i.e., resistant to rust, acid, and heat) between 1950 and 1985 was 6 %. In 1990, total output reached 10^7 t. Special metallurgical processes have been developed for steels with a chromium content 12 – 28 % and low carbon content [65].

Production conditions are determined by the thermodynamic equilibria of the reactions of oxygen with carbon and chromium (Figs. 59, 60).

In the first process variation, which is mainly used in western countries, an electric furnace is used to melt scrap and alloying elements. The composition of the molten metal used corresponds approximately to that of the desired steel product, apart from the carbon content. Decarburization and desulfurization are carried out, either in a converter or a ladle in vacuum, or in a combination of the two (Fig. 61).

The converters are operated by the combined blowing technique (i.e., via top lance and bottom tuyeres) to increase the rate of decarburization. Nitrogen is used as the protective gas for the bottom tuyeres and to reduce the oxygen partial pressure. Argon is used to give low carbon contens and to avoid nitrogen pick up of the steel. After decarburization, the Cr_2O_3-containing slag is reduced with silicon, and the sulfur combines with the lime-based slag. In an

Figure 61. Methods for decarburizing high- chromium melts
AOD = argon – oxygen decarburization; ASM = argon secondary metallurgy; MRP = metal refining process; AOD-L = argon – oxygen decarburization lance; KCB-S = Krupp combined blowing stainless; K-BOP = Kawasaki basic oxygen process; VODC = vacuum – oxygen decarburization converter; VOD = vacuum – oxygen decarburization

alternative process, the premelt is poured from the electric furnace into a ladle placed in a vacuum chamber. Decarburization is then achieved by a stream of oxygen which enters via the lid of the vacuum chamber as the pressure is reduced, and is then blown through a lance into or over the melt.

In the vacuum process, the rate of decarburization reaches 0.03 %/min, a considerably lower figure than that achieved by the converter processes. The latter give high productivity and favorable economics and are therefore, used for high-volume production of crude stainless steels. Vacuum processes are especially suitable for the production of special steels with very low carbon content (30 ppm), and low levels of nitrogen and hydrogen.

A combination of both processes utilizes the high decarburization rate of the converter in the high- carbon content region, and the low carbon levels achievable by the vacuum process.

In Japan, a two-stage process is used for the melt reduction of chromium ores to produce stainless steels (Fig. 62) [66]. Two 85 t combined blowing converters are used. In the first of these, chromium ore is added to a dephosphorized pig iron bath where it is reduced to chromium with coal and oxygen. The carbon-containing chromium melt is tapped and, after slag removal, charged to the second converter, where it is decarburized. The heat of reaction enables added scrap and alloying metals to be melted. The advantage of the combined blowing converter is that, as well as passing oxygen and argon through the bottom tuyeres, it is also possible to decarburize with pure oxygen, as the tuyeres are cooled with hydrocarbons.

Figure 62. Two-stage stainless steel production (smelting – reduction) process

3.4. Secondary Metallurgy

The steelmaking processes described in Section 3.3, with the exception of plasma furnaces, take place in oxidizing atmospheres, and are designed to maximize the output and cost-effectiveness of crude steel production.

The secondary metallurgical treatment processes produce the specific properties required for the various applications of the steels concerned. They include:

1) Adjustment of alloy composition
2) Deoxidation
3) Homogenization of temperature and composition
4) Temperature adjustment
5) Decarburization
6) Desulfurization
7) Degassing
8) Control of inclusion shape
9) Adjustment of purity

The processes take place in the steel ladle, so that the steel production equipment is not involved, and correspond to the quality program and the production plan (Fig. 63) [55].

It is essential that the slag produced during the oxidation processes should be separated cleanly, and that the refractory lining of the ladle should not act as a source of oxygen during the reduction phase, or have a detrimental effect on the composition of the reaction slag.

To hold back the slag formed during the oxygen-blowing process, floating stoppers are used to close off the tap hole. Their function depends on the different densities of the steel and slag; alternatively, mechanical or pneumatic devices can be used. In electric furnaces, there is a curved region or syphon near the tapping hole, or an oval hearth is provided so that no slag is discharged, provided that a residue of 15 – 20 % steel is retained in the furnace.

3.4.1. Steel Treatment at Atmospheric Pressure

Secondary metallurgy requires mixing in the ladle. This is achieved by passing gases through porous bricks in the bottom of the ladle, or by injecting them through refractory- covered lances

Figure 63. Secondary metallurgy processes in steel production
VAD = vacuum arc decarburization

dipping into the melt, thus producing a rising stream of bubbles. A possible alternative is to use the stirring effect of electromagnetic fields acting through the nonmagnetic walls of the ladle. Depending on the amount of mixing energy generated, this can cause circulation and homogenization of the steel under the slag layer, or mixing of the steel with the slag with chemical reaction, e.g., desulfurization. If ladle covers are used, the steel can be protected from reoxidation and falling temperature.

The solid materials can be added in lump form through openings in the ladle lid, or injected in powder form through lances, using a gas as transport medium. For exactly measured additions, solid wire can be added (e.g., aluminum), or wire filled with other substances (e.g., CaSi), which can be added almost without loss of material.

3.4.1.1. Deoxidation

As well as alloy addition, deoxidation (removal of residual oxygen) is necessary in the production of quality steels. Depending on the carbon content of the steel, it can contain 100 – 300 ppm dissolved oxygen, and this is removed by adding elements with an affinity for oxygen (e.g., silicon or aluminum, to form silica or alumina). These oxides are of lower density than steel, but their particle size also greatly affects their upward movement. The deoxidation products are encouraged to coagulate by agitating the steel in the ladle with argon or nitrogen. The ascending reaction products take up the liquid reactive ladle slag. The amount of these materials remaining in the steel determines its oxide content, and affects its mechanical properties. By using a combination of deoxidizing metals, a very low level of oxygen in the steel can be achieved (Fig. 64) [68].

Figure 64. Equilibrium of calcium and sulfur or oxygen in liquid iron at unit activity of CaS and CaO [66], [67]

3.4.1.2. Desulfurization

For high rates of steel production, only a limited amount of desulfurization can be carried out in the blast furnace. When a blast furnace process is optimized for low fuel consumption, the sulfur distribution coefficient between the slag and the pig iron is 20, which, for current mass ratios, leads to a sulfur content of 500 ppm in the pig iron (Fig. 65). Depending on quality requirements, the first step is the injection of lime and other calcium – magnesium compounds into the pig iron ladle. The relatively poor sulfur partition coefficient (ca. 5) in the oxygen injection steelmaking process is due to the oxidizing reactions. However, if the steel has a high enough aluminum content after deoxidation, this gives good reducing conditions. If the correct desulfurizing agents are chosen (CaO, Mg, CaC_2, CaSi), or lime-saturated desulfurizing slags are used, sulfur distribution coefficients of 1000 can be achieved [69]. The desulfurization of the pig iron and steel, especially if both these processes are used, enables the required quality to be achieved flexibly and economically. The use of desulfurizing slags requires intensive mixing of the steel and the slag under reducing conditions.

Figure 65. Process stages for adjustment of low sulfur content in liquid steel

Figure 66 shows the changes in sulfur content in steel produced on a large scale over a number of years [68]. In this example, which refers to steel used for pipes, the development of toughness and sulfur content is shown. The use of calcium compounds under certain conditions leads to the formation of spheroidal inclusions that are not deformed during the rolling process. This has enabled high-strength steels with good toughness properties to be developed.

Figure 66. Development of toughness and sulfur content

3.4.1.3. Dephosphorization

Phosphorus removal is carried out under oxidizing conditions during production of the crude steel, and is influenced by the lime saturation, the P_2O_5 content, and the temperature of the slag produced during decarburization (Section 3.3). The production of low-phosphorus steel requires low-P, low-Mn pig iron, and effective removal of the P_2O_5-containing slag produced during decarburization and before deoxidation.

3.4.1.4. Temperature Control

The temperature changes during steel production affect the course of the reaction (as shown by the example of dephosphorization), and also affect the economics (wear of the refractory linings of furnaces and ladles). The secondary metallurgical operations: alloying, desulfurization, degassing, etc., require time, and therefore involve heat losses. Without ladle heating, this would necessitate the use of unfeasibly high tapping temperatures. Electrically heated ladle furnaces are increasingly used in steelworks – initially in EF steel plants and then in BOF plants – to ensure an optimum temperature regime during the process.

Figure 67 illustrates the increasing use of ladle furnaces [67]. The furnaces consist of an assembly of two or three a.c. or d.c. electrodes, and a water-cooled roof, with fume extraction

equipment, and a working door for adding materials and for the control equipment (Fig. 68) [69].

Figure 67. Ladle furnace development

Figure 68. Typical layout for a ladle furnace

The transformer capacity is ca. 150 kV · A per tonne ladle contents, and gives a heating rate of 5 °C/min. The diameter of the pitch circle has been reduced to 600 – 700 mm in new designs to protect the refractory ladle lining. Agitation of the steel and slag to homogenize the steel, and to promote the steel – slag reactions, is very important in the operation of the ladle furnace. The electricity consumption for treatment time ca. 40 min is 30 – 40 KWh/t, and the amount of electrode material consumed is 0.3 kg per tonne of steel. With a ladle furnace, the temperature at which the steel is tapped can be reduced by 100 °C without affecting the secondary metallurgical reactions.

Figure 69. Equipment for the CAS process
a) Dust- collecting hood; b) Alloy chute; c) Snorkel raising and lowering unit; d) Oxygen lance; e) Bell; f) Porous plug

An alternative to the ladle furnace is the CAS/CAS – OB (Composition Adjustment by Sealed Argon Bubbling) developed by Nippon Steel [69], the IR-UT (Injection Refining-Up Temperature) process proposed by Sumitomo. The heat evolved by the oxidation of aluminum or silicon is used to heat the steel, instead of electrical energy. The process is suitable for producing flat products that are insensitive to hydrogen. After the slag-free steel has been tapped, it is agitated by inert gas, and alloyed in a bell (Fig. 69). If the temperature has decreased too much, the melt can be heated to the required pouring temperature by adding aluminum and oxidizing it

Figure 70. Vacuum treatment of steel

with oxygen. The addition of O_2 at a rate of $11\,m^3\,h^{-1}\,t^{-1}$ gives a heating rate of 7 °C/min.

Figure 71. Final carbon content as a function of dissolved oxygen

3.4.2. Vacuum Treatment

The vacuum treatment of steel is used increasingly owing to its versatility and special advantages, and is indispensable for removal of gases dissolved in the steel, such as hydrogen and nitrogen. The reactions proceed at very low pressure (0.5 hPa). The various processes are shown in Figure 70 [55]. They can be divided into three groups: recirculating treatment of small quantities of metal; ladle treatment; and treatment of a stream of molten metal.

The recirculating processes are characterized by high throughputs. In the RH plant, two refractory- clad snorkels dip into the steel being treated; in the DH plant only one snorkel is used. Whereas in the RH process, the steel is transferred into the vacuum vessel by blowing inert gas via a nozzle (gas lift), in the DH plant the movement of the steel in the vessel is achieved

by the up-and-down motion of the vessel. In both processes, oxygen lances can be provided.

3.4.2.1. Decarburization

The decarburization reaction is strongly pressure dependent, so that when it is carried out under vacuum, fine decarburization is the result. As shown in Figure 71, carbon content < 50 ppm can be achieved reproducibly under optimal process conditions [68].

The required treatment time is strongly pressure dependent. A rapid decrease in pressure is only feasible if the vacuum vessel is fairly large, as the melt splashes severely. If the amount of oxygen dissolved in the steel is insufficient for the decarburization reaction, oxygen is blown in with a lance, liberating heat.

3.4.2.2. Nitrogen Removal

High nitrogen content has a detrimental effect on the deep-drawing properties of continuously annealed mild steel, and also reduces the resistance of tube steels to hydrogen-induced cracking (HIC). The change in nitrogen content during oxygen blowing is shown in Figure 72 [68].

Figure 72. Nitrogen removal

If the nitrogen content in the pig iron is low, nitrogen levels of 30 ppm in plain carbon steels can be achieved. However, steel can pick up nitrogen if nitrogen-containing alloying elements are used, and nitrogen removal may then be necessary. This can be carried out by vacuum treatment under controlled conditions [68]. Nitrogen removal by ladle degassing (after desulfurization) can give a nitrogen content ca. 50 ppm (Fig. 73). Sulfur interferes with nitrogen removal.

Figure 73. Mean nitrogen content before and after vacuum treatment
○ = [N] before ladle degassing; ● = [N] after ladle degassing

The ladle degassing operation gives intensive phase contact between the steel and the slag, which has a beneficial effect on desulfurization. With 10 ppm sulfur and low oxygen content, a nitrogen level of 30 ppm in the steel can be achieved, whether the starting level is 50 or 110 ppm.

3.4.2.3. Dehydrogenation

To avoid flaking (material separation) in the steel, the hydrogen content must be lower than its maximum solubility. For large cross sections, i.e., conditions favoring segregation, it is necessary to reduce the hydrogen content of the liquid steel to < 0.8 ppm. The diffusion reaction is controlled by the difference between the hydrogen partial pressure in the steel and that in the gas at the phase boundary, and therefore proceeds more rapidly as the pressure in the vessel decreases. The formation of new surfaces by intensive purging with inert gas, or otherwise agitating the steel in RH and DH equipment promotes hydrogen removal, as shown in Figure 74 [70].

Figure 74. Hydrogen removal

The choice of steel production and secondary metallurgical processes depends on the product, the production rate, the raw material, and the energy situation. In Europe, high-quality flat products are produced by the route: blast furnace – oxygen blowing – RH or DH vacuum treatment – continuous casting. Long products are mainly produced by the route: electric furnace – ladle furnace – continuous casting. New developments such as COREX – EOF – KES and continuous casting to give cast-to-shape products, promise technological and economic stimuli, especially with respect to the environment.

3.5. Casting and Solidification

3.5.1. Fundamentals

All processes of casting and solidification depend on the basic processes of heat transfer, mass transfer, and interface kinetics. This applies not only to ingot casting, continuous casting, and foundry work, but also to remelting and spraying processes, crystal growth, the production of composite materials from a melt, and rapid solidification to give a crystalline or amorphous structure. These basic principles are valid for all metals and alloys, and the theory is very advanced [71–76].

Nevertheless, steel is special material, having its own characteristic casting and solidification properties that differ from those of both light and heavy nonferrous metals. The peculiarities of steel include: high melting point, low thermal conductivity, phase transformations of the iron, high density, and strong affinity for oxygen. The wide variety of alloy compositions of steel is also reflected in its solidification properties, i.e., the way in which the thermal processes and structure formation take place [77].

A rigorous scientific treatment of heat and mass transfer and interface kinetics cannot be given here, but their most important consequences are indicated, including solidification morphology, micro- and macrosegregation phenomena, sulfide precipitation, and the formation of inclusions by deoxidation. Thermal stress and mechanical deformation also merit consideration, as they particularly affect the quality of the product; processing techniques and mechanical engineering are tailored to suit them.

Solidification Morphology of Steel. The general criteria for the stability of a nominally planar solidification front are: high superheat, convection, low rate of solidification, low content of alloying elements, and a high partition ratio. These conditions are seldom met in casting operations in the steel industry. Much more frequently, there is "constitutional undercooling" at the solidification front, so that steel almost always solidifies dendritically.

Figure 75 shows a scanning electron micrograph of a "quasi-decanted" dendritic soldification front from the central shrinkage cavity of a continuously cast billet of high-temperature steel.

Figure 75. Dendrite morphology in center of a continuously cast billet of steel, grade 10 CrMo 910

The dendritic crystals consist of primary, secondary, and tertiary arms, all with crystallographic growth direction [100]. The dendritic growth mainly determines the spatial pattern of segregation.

Primary and secondary dendrite arm spacings in a typical continuously cast steel slab are shown in Figure 76. Plots of these spacings against distance from a surface of the slab are parabolic, with the widest spacings in the center of the slab.

Figure 76. Variation of dendrite arm spacing in a continuously cast slab of steel, grade API X60, 0.14 % C, 1.50 % Mn

By the method of steady-state unidirectional solidification, typical values for the growth variables affecting the dendrite arm spacings can be determined [78], [79]. In the equations:

$$\lambda = c R^m G^n$$

and

$$\lambda = c \theta_f^n$$

R represents the solidification rate, G the temperature gradient, and θ_f the local solidification time.

Figure 77 shows such a correlation for the primary arm spacings in a steel with 0.15 % C and 1.44 % Mn. Further values of these parameters for selected steels are given in Table 11. These show that high-alloy steels have a finer dendritic structure than low-alloy steels. Figure 78 shows that, for four low-alloy steels (I–IV), the data are in good agreement with equations of the form:

Figure 77. Correlation of primary arm spacing λ_1 with R and G_L for steel II with 0.15 % C, 1.44 % Mn $\lambda_1 = 0.0368\, R^{-0.265}\, G_L^{-0.385}$; λ_1 in cm; R in cm/s; G_L (K/cm) is the temperature gradient at the liquidus temperature

Figure 78. Correlation of secondary arm spacing λ_2 with local solidification time θ_f

$$\lambda_2 = c \theta_f^n .$$

If R, G, and θ_f are known, the segregation spacings can be predicted. Conversely, local cooling rates can be found by measuring the segregation spacings.

If molten metal is undercooled during casting, free crystallites can be generated. This can take place by heterogeneous nucleation, or by the detachment of dendrite arms, which can be

Table 11. Equations for dendrite arm spacings λ (cm) as a function of growth variables R (cm/s), G (°C/cm), and θ_f (s)

Type	Steel composition	Primary arms	Secondary arms	
I	0.09 % C, 1.36 % Mn	$\lambda_1 = 0.0367\ R^{-0.29}\ G^{-0.43}$	$\lambda_2 = 0.01487\ R^{-0.43}\ G^{-0.51}$	$\lambda_2 = 0.00280\ \theta_f^{0.507}$
II	0.15 % C, 1.44 % Mn	$\lambda_1 = 0.0368\ R^{-0.27}\ G^{-0.39}$	$\lambda_2 = 0.00645\ R^{-0.43}\ G^{-0.40}$	$\lambda_2 = 0.00168\ \theta_f^{0.43}$
III	0.59 % C, 1.10 % Mn	$\lambda_1 = 0.1900\ R^{-0.26}\ G^{-0.72}$	$\lambda_2 = 0.01500\ R^{-0.41}\ G^{-0.51}$	$\lambda_2 = 0.00158\ \theta_f^{0.44}$
IV	1.48 % C, 1.14 % Mn	$\lambda_1 = 0.2700\ R^{-0.24}\ G^{-0.72}$	$\lambda_2 = 0.01000\ R^{-0.49}\ G^{-0.51}$	$\lambda_2 = 0.00072\ \theta_f^{0.50}$
V	0.63 % C, 24.9 % Mn	$\lambda_1 = 0.0610\ R^{-0.17}\ G^{-0.36}$	$\lambda_2 = 0.00360\ R^{-0.41}\ G^{-0.37}$	$\lambda_2 = 0.00058\ \theta_f^{0.44}$
VI	0.68 % C, 28.3 % Cr	$\lambda_1 = 0.0280\ R^{-0.25}\ G^{-0.31}$	$\lambda_2 = 0.00320\ R^{-0.41}\ G^{-0.37}$	$\lambda_2 = 0.00052\ \theta_f^{0.39}$

caused by a small degree of superheat, or by inoculation, stirring, jolting, or vibration.

A suspension of crystals in molten steel is shown in Figure 79. The crystallites can redissolve and become globular in form. The globulites settle out during casting and appear, e.g., at the bottom of an ingot or the lower side or central zone of a continuously cast strand. An advantage of this equiaxed structure is that its properties are isotropic.

Figure 79. Formation of free crystals in a steel melt continuously cast with undercooling

Interdendritic Microsegregation. The thermodynamic basis for microsegregation is the change in concentration that accompanies a phase change from liquid to solid, and is expressed by the partition ratios k of the solute elements present in the iron. Kinetic factors include enrichment of the dissolved elements in front of the phase boundary, which depends on mass transfer in the liquid, and the extent of diffusional equilibration in the solid.

The degree of concentration enrichment at the phase boundary $C*_S$, in the case of layer crystal formation without diffusion in the solid, is given by:

$$C*_S = k\,C_0\,(1 - f_s)^{k-1}$$

where C_0 is the starting concentration, and f_s the extent of solidification in the dendritic volume element. The degree of solute rejection is, therefore, determined by k. Typical values of k for the more important elements found in steel are given in Table 12. The elements S, P, and C segregate strongly. With carbon, some concentration equilibration takes place by diffusion.

Table 12. Equilibrium partition ratio k of solute element at solid – liquid interface for δ- or γ-iron

	$k^{\delta/l}$	$k^{\gamma/l}$
C	0.20	0.35
Si	0.77	0.52
Mn	0.75	0.75
P	0.13	0.06
S	0.06	0.025

Segregation can be measured over a large area by computer- controlled automatic electron beam microanalysis. For example, Figure 80 shows a three-dimensional relief map of the manganese concentration in a 25 CrMo 4 steel [80]. The scattered high peaks are caused by MnS inclusions.

Figure 80. Concentration profile of the microsegregation of Mn in a 2.8 t ingot of steel, grade 25 CrMo 4

Modern microanalytical techniques can produce up to 10^6 point measurements within 24 h. In a typical manganese determination, the area investigated can be 80×80 mm, the number of points measured 600 000, the time required 13 h, and the beam diameter 100 µm [81].

Formation of Macrosegregations. Macrosegregations extend over considerably greater distances than dendrite branches. Typical ranges are between the edge and the center or between the top and the bottom of an ingot. The distinction must be made between enrichment and depletion. A systematic discussion of segregration phenomena, including a theoretical treatment, is given in [82].

Positive A- and V-type segregations in cast ingots result from natural convection due to density differences in the enriched liquid over the cross section of the cast material. Stable flow channels can be formed. Sometimes, V-type segregation can also occur in the center of continuously cast strands with equiaxed solidification structure.

In the two-dimensional solidification of continuously cast billets, segregation can take place along the axis of the core. This is associated with shrinkage, and is caused by the growth of dendrites that periodically form bridges that partially seal off the lower part of the liquid metal. Owing to the volume deficit, a powerful suction force is produced toward the crater end. This type of flow restriction does not occur during the one-dimensional solidification of slabs.

Segregation can also be caused by deformation of the outer shell of a strand, e.g., by nonsteady-state bulging outward and rolling back again [83]. This causes a pumping effect in the remaining liquid metal, and leads to so-called central segregation in the slab. Tensile strains at the heterogeneous solidification front cause segregated internal cracking if critical stresses are exceeded. "Soft" or "hard" reduction, to densify the central zone must, therefore, not lead to overstressing of the material below the solidus.

If there is forced convection at the solidification front, e.g., caused by rimming action during ingot casting of unkilled steel (see Section 3.5.2), or by electromagnetic agitation, a washing effect occurs. A depleted streaky layer is produced. With continuous casting, "white bands" are formed.

Depletion is also caused by sedimentation of suspended crystallites, as these are purer than the melt. The accumulation of a conical heap of crystals at the bottom of the ingot therefore leads to "negative" segregation, whereby the axial concentration of alloying elements increases toward the top of the ingot. This happens, e.g., with heavy forging grade ingots.

Sulfide Precipitation. With modern ladle metallurgical treatment, the sulfur content can be brought below 10 ppm, albeit at some cost, by transferring the sulfur into the slag. Any dissolved residual sulfur can be combined with calcium to form stable calcium sulfide, which has no harmful effects on the properties of the product.

Figure 81. Variation of sulfide morphologies in as-cast steel
A) Type I; B), C) Type II; D), E) Transitional types; F) Type III

However, it is not always necessary to have the lowest possible sulfur content, so desulfurization and calcium treatment of the steel can often be omitted. The sulfur then becomes con-

centrated in the interdendritic spaces, owing to its low k value, and eventually precipitates as MnS. The course of the reaction, and hence the form of the sulfide, are determined by the degree of deoxidation and alloy content of the melt, and the local processes of solute redistribution and mass transfer. The various sulfide types in the cast product are [84], [85]:

Type I. Globular oxysulfides that were originally liquid. Formation mechanism: monotectic degeneration. Steel grades: unkilled, semikilled.

Type II. Coral-shaped chain-like sulfide colonies. Formation mechanism: eutectic. Steel grades: killed, low alloy.

Type III. Angular, crystalline sulfide particles. Formation mechanism: "divorced" eutectic. Steel grades: fully killed, high-alloy, containing C, Si, P, Cr, Zr.

The scanning electron micrographs in Figure 81 show typical examples of these morphologies. Types intermediate between II and III can have faceted shapes with branched dendrites.

The size of the sulfide inclusions depends on the local precipitation rate and hence indirectly on the rate of cooling at the solidus temperature. This correlation is illustrated by the log – log plot in Figure 82 [86].

Figure 82. Mean size of sulfide inclusions in steel ingots with 0.55 % C, 2.00 % Mn, 0.009 – 0.039 % S

Formation of Inclusions by Deoxidation. In contrast to sulfide formation during solidification, oxide inclusions are precipitated in the liquid steel at an earlier stage by deoxidation. The amount of dissolved oxygen is reduced to the equilibrium value in a few seconds after the addition of aluminum [87]. As deoxidation proceeds, the inclusions agglomerate or coagulate, and mostly go into the slag. This flotation leads to a reduction in so- called total oxygen.

When aluminum is used for deoxidation, alumina inclusions are formed with a spheroidal or dendritic morphology (Fig. 83) [88]. The coral-like shapes are formed by agglomeration of particles, 2 – 5 µm in size. In steelworks these clusters are referred to as "nests" or "clouds".

Figure 83. Growth morphologies of alumina inclusions in Al-killed steel

The various growth shapes that can be formed under different supersaturation conditions and activities of the oxygen and aluminum are shown in Figure 84 [89]. From left to right, the oxygen level decreases and the aluminum activity increases. At low oxygen levels, the spheroidal oxides initially formed become covered with radiating, stalky, or compact nitrides.

Figure 84. Schematic representation of oxide and nitride morphologies as a function of oxygen level

3.5.2. Ingot Casting

The transition of steel from liquid to solid is mainly achieved by continuous casting. Nevertheless, the older ingot casting process is still used in steelworks all over the world. The molten steel is poured into ingot molds, where it solidifies.

The steel is poured (teemed) from the refractory-lined ladle via a ceramic, closable outlet nozzle. There are two methods of filling the ingot mold. In the top-pouring method, the steel is poured from above directly into the mold, and in the bottom-pouring method, it passes down a central funnel, then through a system of refractory passageways built into a thick steel plate, and passes from below into the ingot molds standing on the plate (Fig. 85) [90].

Figure 85. Top pouring (A) and bottom (B) pouring during ingot casting [90]

The molds can have a rectangular, square, circular, or polygonal interior cross section, depending on the cross section of the profile to be produced by rolling. To facilitate removal of the solid ingot, the mold tapers slightly outward, with the wider end either at the bottom (bigend-down molds) or top (big-end-up molds) (Fig. 86) [91]. Ingots can be 0.1 – 40 t for rolled steel, and up to 500 t for forged steel.

Apart from the cross-sectional shape, the type of ingot mold, and the pouring method, ingots are also characterized according to the physical, thermodynamic, and chemical processes that take place during solidification. Several gases are present in solution in liquid steel. The solvent power of the steel decreases as the temperature decreases, and as the steel solidifies. In ingot casting, oxygen is of particular significance for the solidification process. If oxygen is liberated during solidification, it reacts with the carbon in the steel to form carbon monoxide. This can be partially or completely prevented by combining the oxygen with deoxidants such as aluminum, silicon, or titanium.

If the oxygen is allowed to react with the carbon, the steel product is known as rimming steel. Partial deoxidation leads to "semikilled" steel, and complete deoxidation to "killed steel". Deoxidation to semikilled or killed steel is carried out in the ladle. There is also a combined rimming and killed steel, obtained by first allowing the melt to solidify for some time, and then deoxidizing it in the mold, after which it solidifies completely like a killed steel. This produces "ingot-killed steel".

Rimming Steel. As soon as the liquid steel comes into contact with the walls of the mold and the bottom plate, a thin skin of solid steel is formed. This grows rapidly at first, as the cold mold and bottom plate rapidly absorb heat, and, much later, release it to the atmosphere. After a short time, this compact layer of steel becomes detached from the ingot wall as the solid steel contracts. The gap formed reduces the heat transfer rate from the steel to the mold, and hence the rate of loss of heat to the surroundings. Consequently, the steel solidifies more slowly [92–96].

As the steel changes from liquid to solid, the solubility of oxygen decreases, so that it is liberated and reacts with the carbon present to form carbon monoxide. In addition to the dissolved oxygen present at the start of the pouring process, atmospheric oxygen is picked up by the

Figure 86. Cross sections (not to scale) of the principal types of ingot mold [91]
A) Big-end-down-molds: open top (a) and bottle top (b); B) Big-end-up-molds: open top (c) and closed top (d)

liquid steel during pouring, and during its subsequent solidification; this also reacts with the carbon in the steel. The CO gas bubbles are partly entrapped between the growing steel dendrites, forming so- called edge blow holes, but most of them ascend in the region of the solidification front, combining with other bubbles on their way up. This leads to the formation of a rim of bubbles at the edge of the steel, and an upward gas flow which causes an upward flow of the liquid steel. Thus, the steel in the ingot flows strongly upward at the solidification front and downward in the center (Fig. 87) [97]. This rimming action has led to the name "rimming steel".

Figure 87. Flow pattern in a rimming steel ingot during solidification [97]

In the production of rimming steel, CO should be produced rapidly from the start of solidification, giving a strong flow. If the flow is weak, CO bubbles remain entrapped by the growing dendrites. This causes excessive formation of a ring of bubbles not far below the outer surface of the ingot, which results in the appearance of surface defects resembling cracks when the ingot is processed in the rolling mill.

Apart from oxygen, other elements that are less soluble in the solid state are released at the solidification front. This solute rejection is known as segregation (see Section 3.5.1). The elements that separate out are carried away by the flow of steel, and are concentrated in the remaining melt. This leads to a rim layer of greater chemical purity and enrichment of the segregated elements in the interior.

After a time, the process of gas release (rimming action) is deliberately stopped by placing a heavy steel cover on top of the ingot, or a steel plate, over which water is sprayed. The steel solidifies on the underside of the cover, and forms a dense cap. In the interior of the ingot, gas formation ceases, owing to the increase in gas pressure, and the flow of steel gradually subsides. In the part that still remains liquid, there are detached crystals of very pure iron, formed by redistribution of solute elements. These suspended solid particles sink to the lower part of the ingot, as their density is higher than that of the remaining liquid metal. This sedimentation results in an

equiaxed zone, with a reduced level of impurity elements in the lower part of the ingot. At the top of the ingot, enrichment of elements occurs, e.g., phosphorus and sulfur, which can have a harmful effect on the properties of the rolled product. This marked concentration of elements at the top of the ingot is called macrosegregation.

The ring of gas bubbles formed during the rimming action, and those formed even after the ingot has been closed off, tend to compensate for the difference between the specific volume of the liquid and that of the solid steel. The walls of these cavities have a clean and bright metallic surface, and weld together during subsequent rolling.

These processes during solidification cause the ingot of rimming steel to have a clean edge zone, a rim of bubbles in the lower region, a chemically pure equiaxed region at the bottom end of the interior, and a strongly segregated upper region (Fig. 88) [98].

Figure 88. Distribution of bow holes in rimming steel ingots [98]
A) After slight rimming action: low oxygen content; B) After moderate rimming action: medium oxygen content; C) After vigorous rimming action: high oxygen content

Thus, the ingot of rimming steel has a very inhomogeneous structure. Owing to its clean edge region, it can be used in applications that require a good surface. However, it cannot be used for manufacturing components where a large amount of deformation is involved. This is due to its great inhomogeneity and its aging properties, owing to the residual nitrogen. It is also unsuitable if great importance is attached to welding properties [97–110].

Killed Steel. If the dissolved oxygen content in the steel is reduced by deoxidation until it is significantly less than the carbon present, no carbon monoxide gas can form during solidification, and the steel is said to be killed. In killed steel, there is redistribution of those elements whose solubility in solid steel is lower than that in liquid steel. Some of these segregated elements are enclosed between the growing crystals (dendrites). This is termed microsegregation (see Section 3.5.1).

Convection of the molten metal also takes place during solidification of killed steel. However, this is considerably less intense than in rimming steel, and takes place in the opposite flow direction. In front of the solidification interface, free crystallites move downward along with the liquid steel. The solid particles of steel settle at the bottom end of the ingot, while liquid steel flows upward in the center. As the descending crystals are chemically purer than the remaining liquid steel, a depleted conical heap forms at the bottom of the ingot. Here, the concentration of solute elements is lower than it was in the steel before pouring, whereas the concentration of the solute elements in the upper part of the ingot is correspondingly higher. Thus, there is so- called negative segregation in the lower part, and positive segregation in the upper part of the ingot. This is generally referred to as ingot segregation, and becomes more marked as the ingot cross section increases.

As well as ingot segregation, so- called A- or V-type segregation can take place when killed steel ingots solidify (see Section 3.5.1). Unsteady flow through the network of dendrites sometimes leads to the formation of channels, in which enriched liquid metal solidifies. On longitudinal cross sections of the ingot, these channels appear as A- or V-shaped segregation. The intensity of this type of segregation is dependent on the morphology of the solidified ingot. The finer the dendritic structure, the less marked is A- and V-type segregation.

To prevent the uncontrolled formation of shrinkage cavities in the interior of ingots of killed steel, the steel at the upper part of the ingot (the ingot head) is kept in the liquid state as long as possible. The liquid steel can then flow downward to compensate for the shrinkage of the solidifying region, and cavity formation is prevented.

The reservoir of liquid steel is maintained by reducing the heat transfer from the top part of the ingot to the mold by lining the latter with refractory, thermally insulating, and often slightly

exothermic plates. The loss of heat in an upward direction to the atmosphere is reduced by applying an insulating and/or exothermic powder. Figure 89 shows typical longitudinal sections of steel ingots poured into normal big-end-up and big-end-down ingot molds, with and without a feeder head, or "hot top", of this type [91]. In big-end-down ingots, through-solidification occurs earlier in the upper part than in the lower part of the ingot. This produces axial porosity, which under no circumstance should connect with the outside atmosphere, as this leads to oxide formation in the interior, preventing welding during subsequent rolling operations. Unless the top of the ingot is thermally insulated (hot topping), ingots produced in big-end-up molds form shrinkage cavities which extend deep into the ingot, so that the yield of good material is poor. An ingot from a big-end-down mold without a hot top will have axial porosity.

Figure 89. Types of killed ingot [91]
A) Big-end-up, hot-topped; B) Big-end-down, hot-topped; C) Big-end-up, not hot-topped; D) Big-end-down, not hot-topped

When steels are to be used in applications that require an absolute minimum of interior defects, a hot top of adequate size is essential. For example, when heavy ingots are produced for forging, and are cast big-end-up, a feeder head of thermally insulating material is placed on top, with a volume large enough to prevent formation of a shrinkage cavity in the ingot. Segregation of the remaining molten material then takes place in the feeder head inside the hot top. This part is later separated from the good part of the ingot.

As killed steel is mostly used for demanding applications, there must be as few nonmetallic inclusions as possible. Modern ladle metallurgy, combined with a very high standard of pouring practice, have brought great improvements. If any nonmetallic inclusions remain entrapped, however, these consist mainly of oxidic and sulfidic materials. These can originate from the products of deoxidation, from insulating materials, or are formed during solidification by reactions of the segregation elements. Inclusions in killed steel are mainly found entrapped in the region of the cone of sedimented equiaxed material, at the bottom of the ingot [91], [111–119].

Semikilled Steel. In this type of steel, the ratio of oxygen to carbon content is set by controlled deoxidation, so that the ingot at first solidifies, like killed steel. After a time, the carbon and oxygen become enriched in the remaining liquid, so that the solubility product is exceeded and carbon monoxide is formed. Meanwhile, the ingot head has solidified and is therefore dense, so that blow holes are formed in the interior of the ingot, owing to shrinkage (Fig. 90) [91].

Figure 90. Longitudinal section through a semikilled steel ingot [91]

Semikilled steels are not used for applications with high demands on internal purity and defect-free surface properties [91], [120–122].

Ingot killed steel was developed to combine the clean surface of rimming steel with the low degree of macrosegregation and good aging stability of killed steel. The tops of the ingot molds

are provided with insulating tiles, as with killed steel. The steel is poured undeoxidized into the mold until the insulated region contains a few centimeters of steel. A second and possibly a third mold is then filled in the same way. During this time, rimming takes place in the first mold, as well as solidification of an outer shell of steel, several centimeters thick, which consists of very clean unkilled steel, free of inclusions and segregation. The first ingot mold is then completely filled, while simultaneously adding aluminum in granular form to the stream of metal, thereby mixing it into the liquid part of the ingot. Carried by the central downward flow of rimming steel, the aluminum is transported to the lower part of the ingot. The dissolved aluminum reacts with the oxygen to form coarse Al_2O_3 particles, which rapidly ascend into the highest part of the ingot, owing to their low density. The ingot then solidifies like a killed steel. All the ingots from a heat are poured in this piecemeal fashion.

This process produces an ingot with an outer layer of clean rimming steel, ca. 30 mm thick, and a larger inner region of nonaging killed steel with little macrosegregation (Fig. 91) [123]. This steel can be used when a defect-free surface is required on a nonaging material [123].

Figure 91. Longitudinal section through an ingot of steel killed in the mold [123]

3.5.3. Continuous Casting

In the historical development of continuous casting (strand casting), a breakthrough was achieved in large-scale production by S. Junghans with the invention of the oscillating mold in 1949. This became widely used during the 1970s [124], [125]. By definition, strand casting is a steady-state process in which a strand is continuously drawn out of a mold [126–130]. After the 1980s, development of the conventional continuous casting process virtually came to an end [131–143]. The rolled products produced from continuously cast strand sections are characterized by their extremely good finish and functional properties, are not subject to any particular limitations, and are suitable for a wide range of applications [144].

3.5.3.1. The Growth of Strand Casting

The growth of strand casting worldwide is illustrated in Figure 92. It has already reached $> 60\,\%$ of the total. Up to the 1980s, the competitiveness of steel producers was measured by the proportion of strand casting used. Today, many steelworks use the process exclusively. In many industrialized countries, the proportion is $> 90\,\%$, but in some regions, it is only $20\,\%$ [144].

Figure 92. Development of world steel production, CC output and CC ratio 1970 – 1990
a) World CC-production; b) World crude steel production; c) Share of CC-production, %

The strand casting technique replaces individually cast ingots, blooming and slabbing mills, and semifinished mills. The yield of rolled products per tonne molten steel is increased by 10 – 18 % (see Chap. 1). This technological change has resulted in an excess of crude steel

capacity, but has greatly contributed to energy savings.

Figure 93. Typical cross sections and dimensions of continuously cast strands

Figure 93 shows the shapes and dimensions of some typical strands, with size ranges. Billets are used to manufacture wire or rod. Round bar products are used as the starting material for seamless tubes. Continuously cast blooms are used in the production of profile steel and rails. Case hardening and heat-treatable steels, cold-heading and cold-extruding steels, spring steels, chain steels, rolling bearing steels, and free cutting steels are routinely produced [145]. Slabs are converted into thick plate for pipeline or vessel construction, or processed into hot-rolled wide strip and products made from this, such as cold-rolled thin sheet, which may be surface treated for automobile construction or packaging applications.

3.5.3.2. Productivity

If strand casting accounts for 100 % of the total output of a steelworks, productivity rates become very important. The capacities of the melting, ladle treatment, and casting process must be matched as precisely as possible. If the mix of steel types produced is variable, it must be possible to react to changes with great flexibility.

Modern strand casting plants are characterized by high availability. The utilization ratio, i.e., the ratio of casting time to time available, is 40 – 90 %. In sequential casting, one melt is cast immediately after another without interruption. The ladles are mounted on a turret which swivels, raises, and lowers the ladle (Fig. 94). The molten steel passes through the following items of plant or process steps: ladle – tundish – mold – secondary cooling zone – straightening and withdrawal machine – runout rollers.

Figure 94. Bloom caster with ladle turret

Figure 96. Annual production per strand of European casters (A) as a function of the casting rate per strand for different strand sections (B)

For high productivity, it is also necessary to have a high rate of withdrawal and a long length of the liquid pool. High outputs can only be achieved when bow type casters are used, where the strand, which still has a molten interior, is cast on a circular arc and then straightened to the horizontal position. Figure 95 shows the various types of plant used during the development of the process. Vertical plants (V) have a limited output, owing to the height required. The most usual system is the circular arc plant with a curved mold (CAC), with several straightening points. In a circular arc machine with straight mold (CAS), the strand, with its molten center, is first bent into an arc, and then straightened. The bending and straightening take place progressively. Extremely precise mechanical technology is used to minimize stressing of the cast material.

The production rate for a single strand depends on the format, dimensions, and casting speed (Fig. 96) [144]. For slabs, a rate of 5.5 t/min is possible. This must be matched to the batch time of the basic oxygen furnace. For blooms and billets, the number of strands must be increased to four or six to match this batch time.

Plant availability can be improved by: insertion of the dummy bar from above; design of mold and runout rollers as a quick change unit; flying tundish changeover by means of a swivel device; uninterrupted casting of different steels one after the other without forming a mixed zone (the old strand being joined to the new by a cage-and-anchor joint); and computer-controlled automatic width adjustment of the strand. A high standard of control technology and automation is necessary in the casting plant.

Regular inspection and preventive maintenance ensure problem-free casting.

With slabs and blooms, an average run of nine heats is usual, and with billets, five heats [144]. More flexibility in the production program is provided by a device for longitudinal cutting of slabs, especially for "jumbo" slabs, up to 2640 mm in width. Double and triple casting can also be provided for.

3.5.3.3. Mold Oscillation and Shell Formation

The most important invention in the technical development of strand casting was mold oscillation, which gives the product a good surface finish. Figure 97 shows how the molten steel from the tundish passes through a submerged entry nozzle into a slab mold. The steel flows sideways during slab casting, but vertically downward with square or round mold shapes. The pouring temperature is controlled within a very narrow range.

Figure 97. Steel flow from tundish into an oscillating slab mold
a) Tundish; b) Sliding gate; c) Submerged entry nozzle; d) Copper mold plate

The oscillation of the mold is illustrated in Figure 98. The movement is usually sinusoidal. Stroke and frequency are so adjusted that the mold briefly overtakes the strand during the downward movement. During this so-called negative strip time, the skin of the casting is briefly upset. Any surface damage is completely healed. The negative strip time t_N (an important control parameter) is given by the following formula:

$$t_N = \frac{1}{\pi f} \arccos - \frac{v_g}{\pi f h}$$

where t_N is in s, the frequency f is in s^{-1}, the casting speed v_g in mm/s, and the stroke h in mm. If $t_N \to 0$, tearing of the shell occurs, and if it is too large (> 0.2 s) deep oscillation marks are produced, and lubrication in the gap between the mold and the strand is impaired. When changes to the casting rate occur during unsteady phases, such as the start of casting or ladle changes, the frequency is adjusted. Amplitudes are kept constant at 2 – 6 mm, but frequencies vary around $6\,s^{-1}$. A curved mold oscillates precisely along the arc.

Figure 98. Mold oscillation with definition of positive and negative strip times

Molds are usually 700 – 900 mm long, and are made of high-strength, copper-based mate-

rials. To maximize operating life, the surface is coated with chrome (60 – 80 µm) or nickel (0.5 – 4.0 mm). For small cross sections, tube molds are usual, and for large cross sections, plates are mounted on stable steel frames. To accomodate the contraction of the steel, the molds taper inward. For plants with high casting rates for billets and blooms, very close geometrical tolerances must be adhered to. For sensitive steels with high sulfur content or wide solidification range, the casting speed is reduced.

3.5.3.4. Control of Molten Steel Level and Gap Lubrication

For problem-free strand withdrawal from the mold, the cycle must be optimized, the meniscus level of molten steel kept constant, and an appropriate casting powder must be used to lubricate the gap.

The flow of steel is controlled by sliding gates (Fig. 97) or stoppers. The steel level is detected with the aid of radioactive sources, ^{60}Co or ^{137}Cs, or eddy current detectors, and is controlled within ± 5 mm, or even ± 2 mm, depending on the sophistication of the control equipment, the format of the strands, and the casting rate.

The casting powders used must be appropriate for the types of steel and the casting conditions. On contact with the surface of the steel, they should melt promptly at 1100 – 1200 °C, and form a lubricating film between the strand and the mold. Penetration into the gap plays a key role in the formation of the steel surface for high withdrawal speeds [145].

Casting powders consist of CaO, SiO_2, and $Al_2O_3 \cdot CaF_2$, Na_2O, or Li_2O are added to lower the viscosity. Carbon particles in the form of powdered coke or soot retard the melting. The basicity of the slags is given by:

$$CaO/SiO_2 = 0.8 - 1.2$$

The amount of casting powder required depends on the oscillation cycle, the casting speed, the geometry of the gap, and the viscosity. Slabs are cast by means of low-viscosity slags: 0.1 – 0.3 Pa · s (1300 °C). For blooms, viscosities must be somewhat higher: 0.4 – 1.5 Pa · s (1300 °C).

Casting powders protect the molten steel from radiation heat loss, prevent contact with atmospheric oxygen, and absorb oxide inclusions that rise to the surface, especially Al_2O_3. Powders and granules (nowadays preferred) can be added automatically in the fluidized state.

3.5.3.5. Support Roller Apron and Secondary Cooling Zone

At the mold exit, the skin of the strand is sometimes quite thin, e.g., 10 – 12 mm, depending on the withdrawal velocity, and is ductile and deformable under the conditions of high temperature and ferrostatic pressure. Whereas billets and round bars are dimensionally stable, the wide faces of slabs and blooms tend to bulge, and must be supported by rollers [146].

To prevent excessive thermal stress on the rollers, they are cooled internally. The helirollers contain a spiral channel for circulating the water, and are stable and long-lasting [138]. Divided rollers with intermediate bearings are of smaller diameter and can accomodate narrower gaps between them. Where bending and straightening of the strand is carried out, deviation of the rollers from the ideal line must not exceed 1 mm. Loose-fitting and worn rollers must not cause this limit to be exceeded.

In the secondary cooling zone, the strand is cooled with water sprays. There are various jet systems to provide different flow rates of water impingement. In the extreme, the surface can be sprayed "black". In the early days, large quantities of water were used for fear of break-outs of molten steel. Since then, the water rate has been limited to the minimum required for the necessary cooling intensity. Air/water mixtures are used to achieve gentle and uniform cooling. Specific consumptions of spray water are 0.7 L per kilogram of steel for spray cooling, and 0.1 – 0.2 L/kg for air-mist cooling.

3.5.3.6. Automation

Most functions of a casting machine are automatically controlled. Figure 99 gives an overview of the individual processes [132]. Secondary cooling is dynamically controlled. The

Figure 99. Instrumentation and automatic process control of a continuous casting machine

spray water is adjusted according to the casting speed to prevent undercooling. Cooling water circulation, hydraulic, and lubrication systems are computer controlled. The rate of steel casting is measured by weighing, and cutting of the strand into lengths is optimized with respect to the heads and tail pieces.

3.5.3.7. Quality

The quality of continuously cast steel as a semifinished material for rolled steel production can be assessed by four criteria:

1) Homogeneity of chemical composition
2) Uniformity of steel structure
3) Extremely high purity
4) Defect-free surface

The above requirements are met if the process is trouble free. Solidification can be controlled to be columnar or equiaxed by means of temperature control and the stirring effect of electromagnetic fields, enabling the blooms and billets to have isotropic properties throughout. With slabs, soft reduction is carried out by conical compression of the center.

Contact of air with the steel is prevented by shrouding systems and by covering the molten metal in tundish and mold with powder. Carryover of slag along with the steel from the casting ladle is detected and prevented. The flow of steel in the tundish is controlled such that oxide inclusions separate out. It is also necessary to use stable refractory materials and refined pouring techniques to ensure a high-purity product. For high-output plants, a vertical part of 2 – 3 m in height enhances the flotation of inclusions and gas bubbles.

Materials technology has elucidated the high-temperature ductility of steel from its molten state to the $\gamma - \alpha$ transformation, and mechanical engineering has provided the necessary data on permissible material stresses during casting. By progressive bending and straightening, and suitable roller distances, tensile strain at the solidification front can be kept $< 0.3\,\%$. Critical temperature zones susceptible to surface cracking are avoided by appropriate cooling. Harmful elements, e.g., N and S, are removed from the steel, or chemically combined to form stable compounds.

3.5.3.8. Horizontal Strand Casting

Horizontal strand casting has replaced ingot mold casting for several types of steel which have hitherto been regarded as unsuitable for strand casting [137], [147]. The capital cost of a horizontal strand casting plant is small. The tundish and mold form a single unit, giving complete exclusion of air. The horizontal strand requires neither bending nor straightening.

The special feature of the process is the creation of an "artificial meniscus" at the break ring, where the skin of the casting first forms

(Fig. 100) [148]. The strand is withdrawn stepwise, and the short frozen sections are welded together. The cycle comprises three phases: pulling out, pushing back, and pause. The pushing-back stage allows healing to occur. The design of the machinery must enable the large mass of the strand to be moved with very high precision with respect to both distance and time [149], [150]. Typical round bar dimensions are 150 – 350 mm in diameter.

Figure 100. Creating an artificial meniscus during solidification in a horizontal casting mold

Figure 101. New processes for the production of thin slabs and hot strip

The breaking ring is made of BN, and is not wettable. Useful lives for this item of 4 – 7 h have been reported. The formation of the solidified skin is precisely controlled with the aid of thermocouples. The casting parameters and mold taper must be precisely matched. Nevertheless, the process is flexible with regard to the formats and steel types. It is of interest for small-scale operations, e.g., 3000 t/month in 100 different grades of mild, stainless, or high-temperature steel [132], [149].

Figure 102. Schematic representation of casting mold for thin slabs

3.5.3.9. Hot Charging or Direct Rolling

Not only is conventional strand casting a fully developed process, guaranteeing a high productive capacity, but it offers the opportunity for energy savings by integration with the rolling mill, i.e., utilizing the heat of the strand by hot charging or direct rolling [139]. For this, the operation of the rolling mill must synchronize with the flow of material from the melting shop, the secondary metallurgical processes, and the strand casting plant. The temperature of the cast product is not allowed to fall below 1200 °C. The surface and the interior must be of high quality.

3.5.3.10. Casting Thin Slabs

Under the heading "near net shape casting," the development of casting technology since 1983

Figure 103. Caster for in-line strip production (ISP)
a) Vertical bow-type mold; b) Soft reduction; c) High reduction (three stands); d) Pendulum shear

has aimed to match the thickness of continuously cast slabs more closely to that of the end product [151], [152], i.e., to reduce the amount of metal forming required, and hence to economize on plant equipment [153–155]. Processes for the production of thin slabs or strip are illustrated schematically in Figure 101.

At the heart of thin slab technology is the funnel-shaped mold into which a narrow submerged entry nozzle with side exit openings is inserted (Fig. 102) [153]. The shell of the strand is smoothly deformed in a controlled manner until it leaves the mold, and the gentle contours keep the bending stress small. The strand leaves the mold with plane parallel surfaces in its wide dimension. Thin slab technology is otherwise similar to conventional strand casting, e.g., control of the level of molten steel, supporting rollers, secondary cooling, etc.

3.5.3.11. New Processes for Hot Steel Strip Production

For integrated "mini-steelworks", various processes have been devised for the production of hot steel strip, based on thin slab casting technology. It is generally agreed that a direct link between casting and rolling to produce a finished product in an in-line, multistand rolling mill is impossible, because the casting and rolling speeds cannot be matched. A buffer can be provided between these processes by operating them in two stages.

A compact strip production (CSP) plant consists of a casting machine, a conveying and linking system designed as a roller hearth furnace, and a hot finish rolling mill [154], [155]. The casting machine is vertical, with bending facility. The casting format is 50×1600 mm; the casting speed is 5 m/min. The strand is cut into 45 m lengths, which are loaded at nearly 1100 °C into an annealing furnace, 162 m long. The final rolling temperature is 880 °C.

In-line strip production (ISP) is shown in Figure 103. The thin slab, with a liquid core, is softly reduced in thickness from 60 to 43 mm immediately after the mold [142], [156], [157]. After through-solidification, the strand passes through three graded stands of high-reduction rolling units. Its thickness is reduced to 15 – 25 mm, and it is made into 28 t coils. Before coiling, it can be reheated by inductive heating to a temperature of 1150 °C. The coils are kept hot in furnaces, ready for the finish rolling mills. The hot steel strip has a final thickness of 1.8 –12.5 mm and can be intensively cooled.

The casting – pressing – rolling (CPR) process (Fig. 104), combines a conventional oscillating thin slab mold of the type described above, with a powerful pair of compression rollers to reduce the thickness of the strand, which has a liquid interior, to 15 – 25 mm in a single step

[158]. The hot strand is then rolled to its final dimensions at 1300 °C in a four-high stand.

Figure 104. Casting – press – rolling process
a) Ladle; b) Tundish; c) Mold; d) Descaling; e) Press rollers; f) Bending roller; g) Straightening unit

3.5.3.12. Rationalization

The new processes of hot steel strip production may replace some of the classical "thick slab – hot strip steel mills", but not completely [155]. Hot strip steel produced by the standard method can be divided into: mild steel for cold forming and cold rolling (76.2 %); weldable construction steels (10.5 %); high-strength carbon steels (1.7 %); microalloyed weldable fine grain and tube steels (6.4 %); stainless steels (3.3 %); and silicon steels for electric sheet (1.9 %).

Assuming sufficiently good surface properties of the mild steels produced by the new casting – rolling processes, their suitability for cold forming and cold rolling is beyond question [155]. Of the total amount of hot steel strip listed above, 75 % could be produced more economically. A considerable fraction of the total production could be transferred from large integrated steelworks to mini-steelworks. The forming properties of 21 % of this total are difficult or critical. Further development work is needed; in particular, the alloy compositions of these materials must be matched to the new casting – rolling processes.

3.5.4. Consumable Electrode Remelting Processes

Remelting processes are used for upgrading the quality of steels and Fe-, Co-, and Ni-based superalloys; conventionally made metal bars are transformed, by simultaneous remelting and resolidification, into new materials with superior properties.

Figure 105. Consumable electrode remelting

3.5.4.1. Remelting Processes

Figure 105 outlines the remelting process for steel and superalloys. The metal to be remelted is

first produced by primary melting, secondary refining, and casting processes, including vacuum induction (VIM) and plasma melting and casting. It is introduced into the remelting process as a so-called "electrode", which is normally shaped by direct ingot casting, with or without subsequent rolling or forging, or by continuous casting. Compound electrodes, such as bundles of bars or continuously cast billets may be used, as well as several individual electrodes, to be remelted simultaneously. Addition of deoxidizers or alloying elements (e.g., Al wire, Ti strip, high-nitrogen alloy compacts) to an electrode, to form a compound electrode, is common.

The electrode is heated at one end above the liquidus temperature so that liquid metal droplets are formed. These fall through the reactive environment of the remelting zone to the liquid metal pool, the surface of which is also heated above the liquidus temperature. The liquid metal pool is confined by a heat-extracting crystallizer, usually a water-cooled copper (or steel) mold. Heat extraction causes the liquid pool to solidify slowly into a new ingot, the "remelted ingot". A "mushy zone" is maintained between the pool and the fully solidified ingot.

The remelting rate dm_e/dt of the electrode(s) practically equals the mold-filling rate dm_i/dt of the remelted ingot. This rate is one or two orders of magnitude smaller than in conventional ingot or continuous casting. A typical value for round remelted ingots of diameter D_i is:

$$dm_i/dt = \left(1000\,\mathrm{kg\,h^{-1}\,m^{-1}}\right) D_i$$

A typical ingot for the rolling mill of mass 3000 kg and diameter 0.5 m thus needs a remelting time of 6 h, a big forging ingot (180 000 kg, 2.4 m) needs 75 h; the time is further increased by the necessary "hot topping" at the end of remelting.

3.5.4.2. General Aims of Remelting

Ingot Structure. One aim of remelting is improvement of ingot structure and homogenization of longitudinal and transverse mechanical properties.

Conventionally cast ingots and strands have a predominant direction of solidification, from the surface to the center, with consequent voids and center segregations. To achieve homogeneous and acceptable mechanical properties, high reduction during hot forming is necessary, which limits the final dimensions of the finished products. Because of their low solidification rate, remelted ingots solidify mainly from the bottom to the top (Fig. 105), which presents center voids and segregations and leads to an extremely sound and homogeneous ingot structure. Less reduction is necessary to achieve a sound product, which increases the final dimensions attainable with a given hot forming device (rolling mill, forge).

Cleanliness. The second aim of remelting is the improvement of metal cleanliness, two mechanisms being effective:

1) The heated metal surfaces and the droplets react with the reactive environment. If the reactive environment is high vacuum, degassing and vacuum deoxidation reactions take place, lowering the content of hydrogen, oxides, nitrides, and volatile metallic residual elements (Cu, Pb, Zn, etc.); if it is reactive slag, complex deoxidation, denitrogenation, and desulfurization take place, together with retention of inclusions from the electrode in the slag.
2) Large inclusions, finding their way into the liquid pool, have time to rise slowly to the top, where they are eliminated by various mechanisms. By reaction with the liquid metal, many of the rising inclusions are reduced in size; below a certain particle diameter rising stops, and these inclusions are retained in the solidifying matrix. The remelted ingot has not only a lower total inclusion content, but the maximum inclusion size of the remaining inclusions is much lower than in the electrode material.

Other Aims. Through the introduction of remelting, these processes have often had the special aim of making products previously not possible by conventional means. An important application is the production of high-nitrogen steels, with high-pressure nitrogen (e.g., 5 MPa) as the remelting environment. Another application is production of sound hollow ingots of steels which are difficult to hot-work, by remelting multiple electrodes into a common annular mold.

3.5.4.3. Remelting Apparatus

Table 13 lists the main processes. Most units for general applications are ESR units, followed by VAR units; EBR, PESR, VADER, and PAR are used for special applications. Details of remelting apparatus construction (electrode feeding; round, square, rectangular, and hollow molds; ingot withdrawal; slags; alloy addition devices; automation, etc.) and other processes are given in the references [159–166].

3.5.4.4. Results and Applications

The high cleanliness of remelted steels makes them useful for surgical implants, highly polishable pressing sheets for laminate production, etc. The homogeneity of mechanical properties is good for thick products of ultrastrength structural steels, tool steels, etc. The soundness of the ingot allows large forgings, up to 100 t or more, to be made from a much smaller ingot, compared with the conventional route. Some high-temperature alloys exhibit improved forgeability. High-nitrogen, fully austenitic PESR steels are used for production of large, nonmagnetic retaining rings for electrical power generators. Further applications are listed in [159–166].

During the last decade, steady improvements in conventional melting and casting technologies regarding cleanliness and soundness have taken over many applications; the more economic route of melting, secondary refining, and continuous casting is favored over remelting processes. For sound ingots of up to a few tonnes, the powder metallurgy route has become a competing, albeit more expensive process.

3.5.5. Cast Steel and Cast Iron

3.5.5.1. Cast Steel

Many grades of steel, of various composition, are suitable for casting. The carbon content can be as high as 2 %, but is usually 0.02 – 0.4 %. Casting consists of pouring into refractory molds, and allowing to solidify.

In the production of steel castings, all types of molds and casting processes are used, including hand- and machine-made molds, shell molds, and ceramic molds. Other processes include precision casting by the lost wax process, the full mold process, and centrifugal casting. Castable steel is melted by methods similar to those for rolling and forging steel, mostly in electric arc furnaces lined with a basic refractory, and, less commonly, in induction-heated, crucible furnaces. The processes of secondary metallurgy in oxygen/argon converters or specially designed gas-purged ladles are increasingly important.

In Germany, of all the crude steel produced, 0.6 % is cast. The proportion is similar in other industrialized countries.

Cast Steel for General Applications. These materials are used for components intended for use between − 10 and 300 °C, which are subject to moderate dynamic and impact stresses, e.g., parts for general machinery, wheels and wheel bearings, rolling equipment, and ships' anchors. The most common material in this group is mild steel, though some low-alloy steels are also used. Steels with a low carbon content have good welding properties, which has ensured a wide range of applications for steel castings. It is common to improve the welding properties by reducing the carbon content, and to compensate for this by increasing the manganese content.

Figure 106 shows the temperature dependence of the mechanical properties of unalloyed cast steel.

Cast Steel for Special Applications. Cast steel was formerly at a disadvantage compared with forged and rolled steel for welded construction, in that high-strength grades with adequate welding properties were unavailable. Metallurgical advances in steel production, especially secondary metallurgy, have enabled the production of steels which, after casting and heat treatment have tensile strengths of ca. 800 N/mm^2. They are thus equivalent to rolled and forged steels, and can be welded to them (Fig. 107).

With these properties, the high-strength weldable and castable grades of steel now available are suitable for welded designs in many areas of engineering. Grades suitable for turbines and steam power stations can be used to make castings up to 100 t.

Alloying costs are not high, but they need to have a carbon content of ca. 0.2 % for good welding properties. To ensure that components of all types will have the properties desired, including welding properties, martensitic and lower bainitic structures must be produced, for uniform strength and toughness.

For plain carbon steel castings, the limit of the wall thickness for through-tempering is ca. 20 mm. By the use of suitable alloying elements, this can be extended to ca. 500 mm, although the welding properties are somewhat affected.

Hot-strength, low-temperaure, and stainless grades of cast steel, including austenitic and duplex steels, are produced in a similar way to the rolling and forging steels (see Chap. 6.2).

The tendency of low-temperature nickel steels to give a coarse-grained structure on solidification makes them less suitable for casting.

It is, therefore, recommended that Cr – Mo or Ni – Cr – Mo alloy steels should be used, if possible.

Typical grades of steel for casting have heat- and abrasion-resistance properties which cannot be matched by rolling and forging steels.

Cast steel is regarded as a high-temperature steel if it effectively resists the scaling effect of gases at > 600 °C. Heat-resistant steels can be divided into ferritic and austenitic grades, and alloys based on nickel and cobalt. Ferritic steels are alloys containing 7 – 28 % Cr and 1.7 % Si, and austenitic steels contain 18 – 30 % Cr and 10 – 37 % Ni. High-temperature steels (Fig. 108) are used for components that are highly stressed, both thermally and mechanically, and are subjected, either continuously or intermittently, to corrosive gases at ca. 600 –1150 °C. These materials have made the continuous operation of industrial furnaces an economic possibility. Other areas of use include ore treatment (roasting furnaces), and the cement, petroleum, and petrochemical industries. Heat-resistant cast steel is used for valve cages, and combustion chambers in diesel engines.

Figure 108. High-temperature cast steel for working temperatures above 540 °C
—·= $\sigma_{B/100\,000}$; – – – = $\sigma_{1/100\,000}$ –·–= DVM (Deutscher Verband für Materialprüfung der Technik) creep limit

Cast hard manganese steel (Fig. 109), which contains 1.0 – 1.4 % C and 12 % Mn, was first described in 1888, and has retained its importance up to the present day. In order to develop its maximum abrasion-resistance properties, a cold-hardening process is required, e.g., by impact or pressure working, which can increase the hardness of the abrasion-resistant surfaces from 250 – 300 to 500 HB (Brinell hardness scale). Good toughness properties can be produced by a solution annealing process at 1050 °C, with water quenching.

Figure 109. Structure of cast hard manganese steel as a function of cooling rate

Hard manganese steel is unsatisfactory under conditions of abrasive wear without impact and pressure work hardening, as under these conditions no cold hardening occurs.

Tempering steels are used where components and workpieces undergo mainly abrasion, but are also subjected to impact stress.

Abrasion-resistant cast hard chrome steels have the highest abrasion resistance of all cast steels. They contain 2.5 – 3.5 % C and 15 – 27 % Cr, and attain their highest abrasion resistance after hardening at 900 – 1050 °C, with either accelerated or static air quenching. This group has the lowest toughness of all the abrasion-resistant materials. Components made of this material must not be subjected to transverse stress. Hard chromium steel is used under conditions of predominantly frictional abrasion, and where impact and pressure stresses are small.

3.5.5.2. Cast Iron

Cast iron includes iron – carbon alloys with carbon content ca. 2.8 – 4 %. The carbon is for the most part not chemically bonded to the iron, but is present in elemental form.

Gray Iron. Cast iron with flake graphite, also known as gray iron, is an iron-based material in which the carbon is nearly all in the form of microscopic graphite flakes with a ferritic –pearlitic structure (Fig. 110). In Germany,

this material falls under the DIN 1691 standard, which specifies tensile strengths of 150 – 350 N/mm^2. In the United Kingdom, BS 1452 applies, and in the United States, ASTM A 48.

Figure 110. Structure zones of cast iron

Formation of the graphite and its primary structure, and hence the strength and hardness of the product, depend very much on the cooling and solidification rate, and hence on the wall thickness. However, heat treatment of gray iron is not normally practicable, so this relationship is less important than the correct choice of chemical composition. For gray iron components, the design can only specify the wall thicknesses and the required strength – the choice of chemical composition must be left to the foundry.

Cast iron is poured at ca. 1300 – 1450 °C. When molten, it can completely fill complicated thin-walled molds, reproducing pattern details exactly. Other important characteristics include its property of damping vibration, its good resistance to corrosion by weathering, and its good machining properties.

The amount of cast iron exceeds that of all other cast materials; ca. 40 % is used in the automobile industry. Other applications include mechanical engineering, the building industry (radiators, boilers, sanitary ware, pipes), chemical plant, shipbuilding, and mining. The former demand by steelworks for cast iron ingot molds has been greatly diminished by the introduction of the continuous casting process.

Spheroidal Graphite (SG) Cast Iron. In spheroidal graphite, also known as ductile iron or nodular iron, the free graphite in the ferritic – pearlitic matrix is almost completely in spheroidal form. This is achieved by treating the melt with magnesium. The formation of spheroidal graphite gives very good ductility, unlike the brittle properties of gray iron.

This material, first produced in 1948, is now the subject of the German DIN 1693, BS 2789 in the United Kingdom, and ASTM A 536 in the United States. Its hardness can be increased by heat treatment and tempering. Its mechanical and physical properties place it between lamellar cast iron and cast steel, though it more closely resembles cast steel.

A large consumer of SG iron is the gas and water pipe industry, which produces centrifugally cast pressure pipes and special pieces (elbows, Y-pieces, T-pieces, etc.). The automobile and general engineering industries have an even greater and increasing demand. Rollers, ingot molds, and heavy, thick-walled storage containers for the disposal of radioactive waste are manufactured from SG iron.

A special development, austempered ductile iron (ADI), also known (somewhat inappropriately) as "bainitic" cast iron, has interesting mechanical properties. When its tensile strength is 900 N/mm^2, its breaking elongation is 5 – 12 %; when its tensile strength is 1400 N/mm^2, its breaking elongation is 1 – 2 %. These materials also have very good abrasion properties. The bainitic hardening is carried out in a salt bath at ca. 300 – 500 °C for 20 min to ca. 2 h. As yet, there is no standard specification in Germany, the United States, Japan, or Sweden. A European standard is in course of preparation.

Cast Iron with Vermicular Graphite. In this type of cast iron, the graphite that separates out is mainly in vermicular form. The connection between this type of cast iron and the mineral vermiculite, a magnesium – aluminum silicate, is only conceptual. On heating and expanding, vermiculite swells up to worm-like shapes (Latin: vermis, worm). Expanded vermiculite is used in the building industry as a sound, and thermal insulator, and has no connection with cast iron.

The basic structure of cast iron with vermicular graphite can be ferritic, pearlitic, or a mixed structure. The mechanical properties of the material lie somewhere between those of gray iron and SG iron. Vermicular graphite has been known since the discovery of spheroidal graphite in 1948. Any vermicular graphite in the SG iron structure was regarded as having a harm-

ful effect on properties. Its occurrence indicated the presence of troublesome elements (principally titanium), which limited the formation of spheroidal graphite if the standing time of the melt was inadequate or excessive. This led to fading of the effects of the magnesium treatment, and imperfect formation of the graphite in the interior of thick-walled SG iron castings.

There is no German standard for this material, but local standards exist.

Alloyed Cast Iron. The properties of cast iron can be modified within wide limits by adding elements such as nickel, chromium, manganese, copper, and silicon, which change the metallic structure. Corrosion-resistant and high-temperature grades are used, e.g., in the chemical industry, in furnaces, and in the automobile industry. The cryogenics industry uses low-temperature grades that do not become brittle at temperatures far below 0 °C. The electrical industry has wide-ranging requirements for nonmagnetic materials, and materials with high electrical resistivity.

In Germany, these materials are covered by DIN 1694 (austenitic cast iron) and DIN 1695 (abrasion-resistant alloyed cast iron), in the United Kingdom by BS 3468, and in the United States by ASTM A 439.

White Cast Iron and Roll Casting. In these special grades of cast iron, the carbon in the structure is not graphite, but iron carbide. White cast iron is extremely resistant to abrasion by frictional and grinding effects. These grades are used in a wide range of rolling operations, and in grinding and mixing processes. As these materials are normally not heat treated, the mechanical properties depend only on the chemical composition, even for very heavy and thick-walled components (rolls).

Malleable Iron. Malleable iron castings acquire their special properties by a tempering heat treatment. Malleable iron is formed from an iron – carbon alloy (DIN 1692) whose chemical composition is such that, after solidification, the carbon in the metallic structure of the casting is not free graphite, but chemically combined as iron carbide, Fe_3C. In this condition, the material is hard and brittle, and almost useless. The tempering process causes a transformation of the white iron by decomposition of the iron carbide at the high temperature used. Elemental carbon is precipitated, and is then present in the structure as compact nodules or flakes.

Depending on the heat treatment, two types of malleable iron can be produced: "white heart" malleable iron in which the heat treatment removes the carbon (Fig. 111), and "black heart" malleable iron in which it does not.

Figure 111. Distribution of carbon and development of the structure in white heart malleable iron of various wall thicknesses

Malleable iron can be produced only in castings of limited mass and wall thickness. Mass varies between a few grams and ca. 100 kg. The good machining properties and especially the uniformity and consistency of the useful properties of malleable iron make it highly suitable for production foundries.

Most of the malleable iron castings produced (65 %) go to the automobile industry. In second place comes the building industry (fittings and pipe connectors). Other consumers include the general engineering and electrical industries, and manufacturers of locks.

Melting of Cast Iron. The oldest and most widely used melting furnace in iron foundries is the cupola furnace. It was developed from the early charcoal furnaces, which were sometimes provided with a cover to keep off snow and rain.

The modern cupola furnace is a shaft furnace with height approximately six times its diameter. The inside diameter is ca. 800 – 3000 cm. Most cupola furnaces have melting capacities of 6 – 12 t (Fig. 112), but the largest cupola furnaces produce 80 t/h. Pig iron, alloying elements, scrap castings, and steel scrap, together

with coke (the fuel) and limestone to liquefy the slag and combine with the sulfur in the coke, are all charged in weighed batches into the cupola furnace.

Figure 112. Iron temperature and melting rate as a function of air blast and available carbon for a cupola furnace with specific cross-sectional area 1 m^2

The cupola furnace consists of a strong cylindrical steel sheet outer cover, lined with a thick layer of refractory bricks and rammed refractory material. In the bottom part of the furnace shaft, ring-shaped nozzles (tuyeres) blow air into the incandescent layers of coke, iron, and other materials.

In the melting zone, the metallic raw materials, selected so that the molten cast iron has the desired composition when it flows from the furnace, are mixed. Molten cast iron at ca. 1500 °C and molten slag are then tapped from separate openings into separate containers. The cast iron is usually collected in a large, refractory-lined holding vessel in front of the cupola furnace. The casting ladles can then be filled from this as required. The slag flows into a cast iron skip, and, after solidification, is disposed of on a waste tip. It is sometimes granulated by adding water, or is used to produce slag wool, used as an insulating material.

Modern cupola furnaces use the hot blast system, in which the combustion air is preheated and sometimes enriched with oxygen. This increases the temperature and melting capacity.

In another type of cupola furnace, firing is by gas or oil. The furnace is provided with burners instead of tuyeres. The column of metal is supported in the shaft by a water- cooled grate, located above the burner zone. Ceramic spheres on the grate increase heat transfer by convection, and the molten iron passes over these and drips into the hearth. The cupola furnace is an economic method of melting large amounts of iron of constant or slightly varying composition. The molten iron can be continuously removed from the furnace. To an increasing extent, induction crucible furnaces are used in iron foundries, usually operating at mains frequency (50 Hz) with iron capacities up to 80 t, although most are in the range 3 – 25 t. Furnaces of this type do not absorb electrical energy when empty, and absorb very little when charged with material in small pieces, because no appreciable induced current is produced under these circumstances. Hence, low-frequency crucible furnaces must always have a quantity of molten metal in the furnace (25 % of the total crucible capacity). To start up the furnace, a precast starting block that matches the shape of the crucible is placed in the crucible by means of a crane.

Medium-frequency induction crucible furnaces, operated at 500 – 1000 Hz, are similar to the mains frequency furnaces, except that their capacities are considerably less for electrical reasons. Medium-frequency furnaces are used if rapid melting and heating, melting without starting blocks, or frequent changes of metal grade are required.

4. Forming

Metals, including steel, can be subjected to plastic deformation in the solid state by the application of external forces, i.e., they can be formed into new permanent shapes. Here, the term “forming” or “metal forming” means the intentional and controlled change of the geometry of a workpiece, usually from a simple geometry to a complex one with regard to the shape, size, accuracy and tolerances, appearance and properties. The mass, composition, and state of the material remain unchanged. If, however, the plastic limit is exceeded so that the change in geometry is not controlled, forming with defects occurs, and the desired product is not obtained.

The phenomenon of plasticity results from the crystalline structure of metals. Their engineering and industrial use depends on forming technology.

4.1. Fundamentals

4.1.1. Causes of Plasticity [171], [172]

In defect-free metal crystals, the atoms are arranged in regular lattice structures.

Plastic deformation takes place when lattice planes slide over each other under the influence of shear forces. The lattice structure remains unchanged, but stepwise slippage occurs at the crystal edges, and these ultimately lead to changes in shape. In metals produced by the usual processes, lattice defects are present (holes, interstitial atoms, dislocations, grain boundaries, twinning boundaries, and interphase boundaries). The dislocations lead to a reduction by two or three orders of magnitude in the stresses (and hence the forces and energies) needed to cause deformation, compared with an ideal, defect-free crystal. However, plastic deformation leads to an increase in the number of dislocations; increasing hardness as the extent of plastic deformation increases. The other lattice defects hinder plastic deformation, thus increasing the hardness. Grain boundaries are an exception to this, being associated with "creep", a very slow form of plastic deformation.

4.1.2. Workability

The properties that enable a material to undergo more or less plastic deformation under given circumstances are grouped together under the term "workability". The two most important characteristics that determine workability are the yield stress and the formability.

The yield stress k_f is defined as the uniaxial tensile stress required to cause plastic flow. Its magnitude, like that of other material properties, mainly depends on the structure of the material, and hence, on its chemical composition [173]. As the structure depends to a large extent on the previous history of the material, i.e., the thermal and forming processes, these processes provide an effective means of influencing the structure and hence the properties of the material (Section 4.1.6). On the other hand, these phenomena mean that the yield stress is not a constant property of the material, but changes during forming. Thus, it also depends on the instantaneous temperature, the degree of plastic deformation, and the previous changes to both these quantities.

Figure 113. Stress – strain curves
A) Typical cold stress – strain curve; B) Typical hot stress – strain curve; C) Effect of temperature on yield stress; D) Effect of strain rate on yield stress at hot-forming temperature

These complex interactions make it extremely difficult to express the yield stress as a function of all the parameters that affect it, or to enable it to be determined with certainty for a given situation. Mostly one is content with a simplified view, in which yield stress is determined

and quoted as a figure that depends on the instantaneous temperature, strain, and strain rate. Attempts are being made to provide a comprehensive treatment of the problem [174], [175].

The yield stress is shown by the degree of strain φ in the flow curve, usually at constant temperature θ and strain rate $\dot{\varphi}$, although graphs of $k_f(\theta)$ and $k_f(\dot{\varphi})$ are also possible.

In cold forming, the material becomes harder with increasing strain (mainly due to an increase in dislocation density). However, the effect of the strain rate is negligibly small. As the temperature increases, the hardness and yield stress decrease. In hot forming, thermally induced hardness reduction processes take place in opposition to the hardness increase described above. This causes the stress – strain curve to remain constant above a certain amount of strain, or to decrease to a lower, approximately constant level after reaching a maximum (Fig. 113). Also, the strain rate has a much greater effect during hot forming than it does at room temperature.

Formability means the extent of plastic deformation φ_B, which a material can undergo without damage (fracture or cracking). This depends not only on the material (chemical composition and structure), but also on the temperature and stress condition during the entire forming process, and is therefore regarded as a property of the system [172]. There are at present no figures available for the quantitative indication of formability. Comparative assessments of materials are made with the aid of such quantities as the reduction of area after fracture, the number of rotations required to cause fracture in torsion tests, or the degree of deformation on fracture calculated from these figures. It has not yet been possible to use these figures to represent relationships in other forming processes. This is also due to the fact that formability is affected by temperature and deformation history. Formability increases with increasing temperature, and also with increasing compression component in the tensile state. The effect of strain rate is usually small, and the nature of the material determines whether formability increases or decreases with increasing strain rate.

4.1.3. Cold Forming

In cold forming, no heat is applied to the workpiece before forming. However, its temperature can increase during the forming process, as the energy expended in forming is almost completely converted into heat. Frictional energy at the contact surfaces of the workpiece, if established, is also converted to heat. In rapid adiabatic processes the temperature can increase by $> 100\,°C$.

The advantages of cold forming include:

For the workpiece:

- Good dimensional accuracy and close tolerances
- Good surface properties
- Very small dimensions (sheet thickness ca. 10 µm, wire diameter ca. 10 µm)
- Work hardening (if desired)

For the tool:

- Reduced wear (effective lubricants can be used, the thermal load is low, and scaling does not occur)

Generally:

- No energy is required for heating the workpiece

4.1.4. Hot Forming

The term hot forming is used when heat is applied to the workpiece before forming. In general, the temperature for hot forming is higher than the recrystallization temperature. If the temperature is too high, a coarse-grained structure can be formed, which is undesirable (Section 6.1.1).

The advantages of hot forming include:

1) Improved formability of the workpiece
2) Smaller forces required, as the yield stress of the workpiece is less
3) Large degree of deformation possible in one forming step, with consequent reduction in processing time
4) Beneficial effect on the structure, and hence on the properties of the workpiece
5) Little or no work hardening (if this is not desired)

The most significant disadvantages of hot forming are:

1) Very high cost of heating the workpiece compared with the energy required for forming
2) Capital investment for the heating furnaces
3) Very severe tool wear due to the very hard and brittle scale that forms on the surface of the workpiece
4) Reduced working life of the tools due to the thermal load and increased wear

Warm forming in the temperature region between room temperature and the recrystallization temperature is similar to hot forming. It represents a compromise between the advantages and disadvantages of hot forming (reduced yield stress, increased formability, little or no scale formation, and effectiveness of lubricants).

Figure 114. Principles of forming
A) Stretching; B) Upsetting; C) Rolling; D) Drawing; E) Extruding; F) Twisting; G) Shearing; H) Bending; I) Deep drawing

4.1.5. Forming Processes

Forming processes must provide a tensile state that causes plastic deformation. The yield stress of the workpiece must be exceeded as well as the friction losses, which depend not only on the coefficient of friction in the contact area between workpiece and tool, but also on the geometry of the forming zones. If the geometry of these zones is unfavorable, friction losses can cause the work of forming to be many times the ideal forming energy, e.g., if a very thin sheet is rolled between relatively large rolls.

Especially during the forming of brittle workpieces, the tensile state must have a large compression component to increase the formability of the workpiece. This has led to the development of forming processes in which compression effects predominate, such as extrusion pressing or shape rolling.

According to DIN 8580, forming is one of the most important manufacturing processes, along with casting, cutting, joining, surface coating, and modification of material properties.

In DIN 8582, forming processes are classified according to the stress state:

1) Compressive forming (mainly massive forming processes): rolling, forging, die forging, extruding
2) Tenso- compressive forming (massive forming and sheet forming processes): wire, rod, and tube drawing (through tapered tools), and deep drawing of flat sheet to produce more complex components
3) Tensile forming (of sheet and rods)
4) Bending (of sheet and rods)
5) Shear forming (mainly massive forming)

The forming processes listed above are based on the principles of stretching, upsetting, rolling, drawing, extruding, twisting, shearing, bending, and deep drawing (Fig. 114).

In DIN 8583 – 8587, the individual forming processes are defined and explained. International and national guidelines and standards that correspond to the DIN standards are not known.

4.1.6. Aims of Forming Technology

Forming technology has developed out of one of the oldest hand-finishing operations, i.e., manual

metal working as applied to jewelry, tools, and weapons, and has led to the almost completely mechanized and automated manufacturing processes of the metal industry that enable dimensionally accurate, high-value products with special properties to be manufactured economically. It competes with other processes (casting, cutting, and joining), and, with increasing scarcity of raw materials and energy, it helps to meet the demand for cost effectiveness.

4.1.6.1. Combination of Casting and Forming

In the usual method for producing steel sheet and strip, slabs 1500 – 2000 mm wide, 200 – 300 mm thick, and 10 – 15 m long are produced by casting (usually continuous casting, Section 3.5.3). After intermediate storage, the slabs are usually reheated to 1100 – 1250 °C before shaping in a rolling mill, first in the blooming train and then in the finishing train, using a total of 10 – 15 rolling passes, to give a strip 1.5 –15 mm thick. Cold rolling is then carried out if thinner products and/or special properties are required.

The improved process consists of casting "thin slabs" (ca. 50 mm thick), or even strip 2 – 20 mm thick, and (sometimes after temperature equalization) rolling this with just sufficient passes to give the desired final thickness, structure, and dimensional accuracy. This conserves the heat energy for reheating the slabs, and the mechanical energy for the rolling stages; it also leads to savings in plant investment costs.

4.1.6.2. Thermomechanical Treatment

Thermomechanical treatment (TMT, see also Section 6.1.3.2.6) is described in DIN 17 014 as a combination of forming and heat treatment aimed at avoiding reheating, reducing the time and equipment required, and improving the properties of the product. In some cases, smaller amounts of expensive alloying elements need to be used. Several processes with various objectives are used for different grades of steel. For example, with "normalizing forming" of structural steels, a structure can be produced that would otherwise require additional heat treatment. The properties of high-strength structural steels can be improved by "thermomechanical forming." Hardening from the hot-forming temperature of high-strength structural steels and the "controlled cooling" of ferritic – pearlitic steels and special steels after such a heating process leads to improvements in their properties and the avoidance of heat treatment [176].

Most large-scale TMT procedures can be divided into three groups [177]. According to the temperatures used and the point on the time – temperature – transformation curve used for the forming process, the processes are referred to as high-temperature thermomechanical treatment (HTMT), low-temperature thermomechanical treatment (LTMT), and isoforming.

4.1.6.3. Simulation of Forming Processes

The increasing capacity of computers enables technical parameters associated with forming operations to be calculated, by sophisticated computational techniques, such as the finite element method. This gives increasingly accurate forecasting of integral parameters, such as forming forces and forming power, enabling plant design and utilization to be planned. Local temperatures, stresses, and strains can also be calculated. Even at the planning stage, statements can be made about local loads on materials, so that any necessary corrective measures can be tried out if these loads represent failure conditions. The same procedure can be applied to the fill behavior of grooved rolls and forging dies.

Algorithmic optimization, supported by modern computers, enables technical objectives to be realized during the planning stage, and can, for example, help in the design of the grooves for a pass sequence. Information systems can also provide expert knowledge not formulated algorithmically.

4.1.6.4. Quality Information Systems

Particularly in multistage sequential finishing lines with quality information systems, the quality criteria achieved in the separate process steps are linked by information technology to the associated process parameters. The resulting picture of the whole process enables the causes of

defects to be identified much earlier, so that production flow can be optimized.

4.2. Hot Working

4.2.1. Reheating Furnaces

The various types of fuel-fired reheating furnaces employed in rolling mills are used to heat the rolling stock as uniformly as possible for a preset period to give a temperature on discharge appropriate for the forming process. Moreover, these heating and soaking processes must take place with optimum energy utilization, minimum cost, little scale formation, and no unwanted surface decarburization. Surface defects, such as skid marks formed during movement of the rolling stock in the furnace, must be avoided.

Furnace construction and thermal design depend on the condition of the charge material and the particular needs of the rolling process. The most usual types of continuous reheating furnaces [178–180] are the top- and bottom-fired pusher type, walking beam, and rotary hearth furnaces. The rolling stock can be of various sections, lengths, masses, and steel grades, e.g., slabs 160 – 260 mm thick, billets 100 – 330 mm edge length, and round bars 175 – 550 mm diameter. The discharge temperature is normally 1200 – 1250 °C for most hot-forming processes. Pusher type furnaces have a maximum output of 300 t/h, walking beam furnaces 450 t/h, and rotary hearth furnaces 120 t/h.

Depending on the output and complexity of reheating furnaces, the heating process is subdivided into several zones, whose temperatures are controlled separately. In the gas flow direction, there is usually a preheating zone, one or more heating zones, and a soaking zone. In pusher type and walking beam furnaces, these main zones are subdivided into upper and lower zones, and sometimes left, middle, and right zones. In general, the furnace control over the whole range of outputs and steel grades should give a uniform heating rate of the workpiece as it passes from the inlet to the exit of the furnace.

Heating is mainly by natural gas, which can vary in composition. In integrated steelworks, coke oven gas, converter gas, and mixed gases are used, or liquefied gas or heating oil.

Developments in furnace technology and heat conservation, especially during the last 10 years, have led to new or modernized reheating furnaces, operating under computer control [181–187]. The aims of computer control include: minimization of energy consumption; temperature equivalence (especially during nonsteady operation); reduction of scaling; minimization of personnel workload; increased output; matching input and output rates within a furnace group; quality assurance; and documentation. These aims can be achieved with the aid of various furnace control strategies, e.g., using the temperatures of the furnace room or of the surface of the rolling stock, and fuel flow rates and parameters derived from these. In models of this type of furnace operation, external information about processes taking place before and after reheating must also be considered. Material flows inside and outside the furnace must be monitored accurately.

Process computer control means using a supervisory computer to monitor and control the plant, implementing mathematical models to optimize the control parameters. In the process control concept for continuous reheating furnaces (Fig. 115), the actual state of the process is calculated with the aid of a mathematical model from the measured process parameters, material flow data, and physical characteristics of the fuel, combustion gas, and charge material. From this, a second mathematical model calculates the optimum control set point for the heating process. These depend on set values, e.g., of the desired cycle time and required final temperature. Disturbances and planned or unplanned interruptions are also included. A special characteristic of this kind of furnace operation strategy is the use of a volume rate of combustion air, which depends on the mixing ratio of the various fuel gases, as a setpoint for the subsidiary control circuit.

The complexity of the hardware and software depends on individual needs. Integration of the process computer to the basic automation system has been progressively simplified.

Potential Energy Savings. Continual improvements in design, construction materials, heating and combustion techniques, and thermal economics have optimized the process of heating the material, with simultaneous reduc-

Figure 115. Data flows in a computerized process control system for a continuous reheating furnace

tions in energy consumption and energy-linked emissions.

Figure 116. Development of the specific heat consumption of walking beam furnaces for heating slabs

Figure 116 shows the changes in the specific heat consumption of walking beam furnaces for heating slabs for rolling mills producing hot-rolled strip, thick plates, and beams. The heat consumption over a complete operating cycle is estimated for cost calculation, including the energy used for heating the furnaces and maintaining them at temperature. The scatter is mainly a consequence of differences in furnace layout, the extent of energy recycling by media preheating, and the benefits resulting from waste heat utilization. Heat consumption is also affected by, for example, heating requirements, fuel qualities, rolling mill operating, and the considerable fluctuations in workload associated with the economic situation.

The following discussion gives an overview of the most important steps to save energy, and enables a systematic, quantitative comparison of the individual steps to be carried out. Calculation of potential savings involves both observed figures and estimated values. Figures are based on a reheating furnace of average design and operation.

Increase in Furnace Length. The most important design characteristic is the length of the furnace, and hence the specific load

($kg\,m^{-2}\,h^{-1}$). The optimum specific load is $500-600\,kg\,m^{-2}\,h^{-1}$, depending on the heat consumption and capital cost. An unheated zone at the charging end (preheating zone), to reduce the temperature of the waste gas at the furnace exit to ca. 750 °C, increases the effectiveness of heating and hence utilization of the fuel.

Increase in Preheating Temperature of the Combustion Air. A temperature rise of 150–200 °C, i.e., up to 600 °C, leads to a saving of ca. 15 % in heat consumption. The waste gas temperature at the exit of the recuperator should not fall below 200–300 °C. This is necessary for an energy-saving natural draft, and avoids low-temperature corrosion in the waste gas system. The furnace design enables the combustion air and the preheating zone to be jointly optimized.

Subdivision of the Furnace into Individually Controlled Zones. This enables the heat consumption in the various furnace zones to be optimized, so that the charge material can be heated at as late a stage as possible. This gives an increase in flexibility, a reduction in heat consumption, and better conditions for computer control.

Uniform Distribution of Fuel and Combustion Air to the Burners: Choice of Burners. The objective is to obtain a uniform flame temperature and hence higher heat transfer, with consequent energy savings. Local overheating and scaling problems can be avoided in this way.

The burners selected should be controllable over a wide range, enabling the temperature in the furnace room to be as uniform as possible. Specially optimized burners have been developed to minimize NO_x production.

Optimization of Fuel/Air Ratio and Furnace Draft. To minimize heat consumption, it is essential to monitor the furnace draft closely, and to reduce air leakage. The ratio of fuel gas to combustion air must be controlled. A precondition for this is that the charge and discharge doors should be as leak-tight as possible. An improvement in the control of this ratio can give ca. 10 % saving in energy for each 2 % reduction in oxygen content.

Improvements in Furnace Linings. In many cases, a large reduction in heat loss through the furnace walls and top can be achieved by additional or improved insulation. A reduction in heat consumption of ca. 2–4 % is attainable.

Improvements in Insulation of Movement and Transport System. This technique is especially effective in prolonging the working life of the equipment. The utilization of waste heat from the movement and transport system for steam production reduces the amount of energy consumed by the steelworks.

Use of Process Computers to Optimize Control of the Heating Process. The introduction of a process control system reduces heat consumption by 5–10 %, and gives constant, reproducible heating and heat penetration of the charge material, especially during nonsteady furnace operation. The process computer optimizes furnace operation, especially in the event of disturbance or interruption.

Reduction of the Discharge Temperature of the Heated Product. This can reduce heat consumption by 10 % per 90 K. The use of lower product temperature is sometimes limited by metallurgical factors, and the requirements of subsequent forming operations.

Increase in Charge Temperature. An increase in the temperature of the charge material reduces heat consumption by 10 % per 140 K, with a potential increase in output. A precondition for the use of hot charge material is that its surface must be defect free. Technical and quality requirements of the material, and technical and logistic capacity of the available plant largely determine whether this considerable potential for energy saving can be realized.

Figure 117 shows a walking beam furnace for heating slabs for a medium-width strip mill, and illustrates the present state of development of the design of this type of plant with energy optimization. The advantage of this construction is its flexibility of operation. Rolling stock of very different thicknesses can be treated simultaneously. If necessary, the furnace can be emptied rapidly. Charging and discharging of workpieces can take place independently. Surface damage by the skid rails at points of contact with the rolling stock is avoided.

Characteristics of an Energy-Optimized Furnace Design. A reheating furnace should fulfill the following requirements. The furnace profile should be box-shaped. The doors should seal as well as possible, to minimize escape of flames and air leakage. To reduce skid marks, the carrier rails should be staggered as far as the furnace exit. To give uniform distribution of the fuel gas, the upper furnace should be provided with roof or side burners, and the lower furnace with side

Figure 117. Longitudinal section of a top-and-bottom-fired, eleven-zone walking beam furnace for heating slabs

burners, sometimes in combination with front burners. The furnace should be subdivided into a large number of controlled zones, especially at the charge end. The possibility of shutting off pairs or rows of burners enables the heated length of the furnace to be matched to the load, with the further advantage that the other burners in the working area can be operated. When deciding on the length of the furnace and hence the load on the hearth area, the possibility of using hot charge material must be borne in mind. If the furnace is to be constructed for mixed hot and cold charge material, its length is determined by the cold charge material; the hearth area output is chosen so that, at 75 % of maximum output, the energy consumption of the furnace is a minimum. The exhaust gas temperature should then be ca. 750 °C. The temperature of the preheated combustion air should be 550 °C, so that the quality specifications of burners and pipework need not be particularly high. The furnace should be provided with equipment for oxygen monitoring, not only in the exhaust gas system, but also in the preheating zone. With such a furnace, a specific net energy consumption of < 1.1 GJ/t is possible, even with cold charge materials and discharge temperature 1250 °C. Heating should be under computer control, and appropriate for the charge material.

Future Prospects. The increasing integration of the processes of steel production, including strand casting, heating and soaking of the workpiece, and forming in the rolling mill, is leading to a unified continuous process to optimize the finished product. With flat products, further energy saving can be obtained by near net shape casting. The current practice of producing slabs up to 260 mm thick, is likely to be replaced by casting thinner slabs. The first industrial-scale plants for thin slab casting are in operation. Compared with a conventional hot-rolled strip mill, considerable energy savings can be realized by producing thin slabs that do not require much energy for the reheating furnace, or electrical energy for the rolling mill. Realization of these energy savings depends on the speed at which these new developments in the production of the steel grades demanded by the market can be implemented.

4.2.2. Hot Rolling

4.2.2.1. Semifinished Products

Definitions. Semifinished products are produced by rolling (more rarely by forging) slab ingots and blooms, and are suitable for rolling into flat and long finished products, and also for making forgings. They can also be produced by continuous casting, followed by rolling or forging.

Slab ingots are products with an approximately rectangular cross section, of width at least twice the thickness. Their mass is 10 – 30 t. Slab ingots are mainly used for the production of flat semifinished products.

Blooms, or ingots with square or rectangular cross section, are used for the production

of rolled semifinished products. Their width is less than twice their thickness, and their mass 3 – 10 t.

Semifinished products for rolling are classified according to their cross-sectional shape (EN 10 079) into:

1) Square products with > 50 mm sides
2) Rectangular products with a cross-sectional area > 2 500 mm^2 and width/thickness < 2
3) Flat products normally > 50 mm thick, width/thickness > 2
4) Profiled semifinished products for producing large profiled finished products, the cross-sectional shape being preformed

Production of Semifinished Products. Semifinished products are produced in slabbing mills and blooming mills. The raw materials are heated to ca. 1300 °C in soaking pits, and formed in 15 – 30 rolling operations (passes) through a heavy two-high reversing stand. The forming process is accompanied by densification and grain refinement of the structure produced on solidification. The rolls have diameter 1000 –1250 mm, the length of the roll body being 2500 –3000 mm. The rolls are provided with box grooves of various widths, and with a plain cylindrical section for rolling flat products (see Fig. 125 A). The material to be rolled is moved along roller tables, positioned with the aid of manipulators, and fed into the roll gap. The material is rotated repeatedly by 90° about its long axis during the series of passes.

There are differences between slabbing stands and blooming stands associated with the product, the most important being the greater height of the stands used for rolling slabs, owing to the necessary lift height of the upper roll and the grooving of the rolls.

The rolls in slabbing stands, mainly used for producing flat semifinished products, have a wide, cylindrical working surface designed to accommodate the widest semifinished slab to be produced, and also two or three box grooves.

Another rolling system is the universal slabbing stand. Working pairs of rolls are arranged horizontally and vertically in succession. The vertical rolls form the narrow sides.

The rolls for blooming stands have a much narrower cylindrical part, and a larger number of box grooves.

The torque required for the forming operation is usually provided by electric motors. These can be twin-drive motors, i.e., one for each roll, or the torque can be transmitted from one common motor by means of a pinion stand.

The rolled semifinished products are cropped with shears at both ends, and divided into ordered lengths. Cropping losses, associated with both forming and metallurgical effects, amount to ca. 10 – 15 wt %. Surface defects are removed by flame deseaming (scarfing).

Square and rectangular semifinished products with cross-sectional areas < ca. 40 000 mm^2 are then usually rolled at 1050 – 900 °C, without intermediate reheating, in the stands of a semifinished-product mill until the desired dimensions are obtained. These trains of rolls are open, semicontinuous, or continuous, as required (see Fig. 126).

With the growth of continuously cast products, the number and importance of slabbing, blooming, and semifinished-product mills is decreasing.

4.2.2.2. Flat Products

Definitions. Flat products have a rectangular cross section with width several hundred times the thickness. The surface is technically smooth, though sometimes a regular pattern of raised or depressed areas can be produced (checker plate, button plate, or stud plate).

This group of products includes:

1) Wide flat steel plate
2) Plate
3) Hot-rolled strip

Wide flat plate is a flat product with thickness > 4 mm, the upper limit being ca. 60 mm. The width is 150 – 1200 mm. EN 91 gives a specification for the edge sharpness. Since wide flat plate is now mainly cut from plate or hot strip steel, the cut or burned edge must meet this specification. The rolled product formerly obtained with a universal roll stand (sharp edges produced by vertical rolls) is seldom used.

Hot-rolled flat products supplied in sheets with minimum width 600 mm are known as sheet metal. The minimum thickness is 3 mm and the upper limit is ca. 150 mm, these products being known as thick or heavy plate. Plate up to ca.

20 mm thick can be cut from hot-rolled strip, if the width does not exceed ca. 2 m. For sheets < 3 mm thick, known as thin sheets, this is almost always done.

The maximum possible width depends on the width of the rolls. This dimension is used when naming the rolling mill, e.g., a 4.2 m heavy plate rolling mill.

Hot-rolled strip is defined as a product which, after the last rolling pass and after passing through a cooling stage, is formed into a coil. As with plate rolling mills, the width of the rolls is an essential characteristic. The maximum width of this type of product is ca. 2 m. For example, a plant is referred to as an 88 inch hot-rolled strip plant, the roll width being quoted in inches by international convention.

The European standard EN 10 079 makes the distinction between hot-rolled wide strip (width > 600 mm) and strip steel (width < 600 m, formerly medium and narrow strip).

The second group of these products can also be produced by cutting wide strip longitudinally.

Another very important characteristic is the specific coil mass in kilograms per millimeter strip width. This is derived from the maximum possible diameter of the coil, and is 20 – 30 kg/mm.

As rolled wide strip mills exceed medium and narrow strip mills in both number and output, the following description of hot-rolled strip relates to the first product.

Production Methods: General Features. Hot-rolled flat products are produced by hot forming flat semifinished products (roughly rolled or continuously cast slabs). Exceptionally (e.g., for heavy plate > 100 mm thick), slab ingots > 30 t are used because of their large mass, and because the required degree of deformation can be achieved. This raw material is heated to ca. 1300 °C.

Hot-rolled flat products are produced almost exclusively on four-high stands. Depending on the thickness of the slabs, the plain working rolls have diameters of ca. 700 mm for hot-rolled strip and 1000 mm for heavy plate, and are provided with considerably larger backup rolls (ca. 1500 – 2500 mm diameter) to prevent severe bending, or even breakage, of the rolls. In this way, the greater stretching action obtainable with thinner rolls can be utilized. The torque necessary for the forming action is transmitted from the drive motors to the working rolls.

In heavy plate rolling mills, where the semifinished slabs used are very wide and there is a large reduction in thickness at each pass, large rolling forces and hence torque values are required. The working rolls have one drive motor each (twin drive). This is also the case for the cogging (roughing) stands of hot-rolled wide strip mills. When torques permit (e.g., in the finishing stands of hot-rolled wide strip mills), pinion stands are used.

Production Process: Plate. The rolling process for producing a single sheet is illustrated in Figure 118. The required width of the sheet is first produced from the slab by deformation in the width direction (finished width plus the extra width at the side required by the process). The rolling stock is then turned by 90°, and stretched in the longitudinal direction to the required thickness. The edges of the sheet do not undergo a fixed amount of deformation, i.e., they are free spreaded.

Figure 118. Principle of rolling single sheets
A) Rolling to required width; B) Rolling to required length or thickness

The shaping process in a four-high stand is achieved by many passes between the working rolls, the thickness being reduced at each pass by operating the screw-down gear, and reversing the direction of rotation by reversing the main drive (reversing mill). Heavy plate mills can have a

cogging stand and a finishing stand (two-stand reversing mills).

The rolls in heavy plate mills have maximum width ca. 5 m. Plates of this width are necessary for the production of large, longitudinal-welded pipes. Narrow sheets are usually obtained by cutting double-width sheets longitudinally. The length of a rolled single sheet depends on the thickness and maximum mass of the slab, and can reach ca. 40 m.

Under the influence of the rolling force, the rolls bend (in spite of the backup rolls), so the middle of a sheet is usually thicker than its edges. To reduce this thickness difference, a bending device is used as well as other technical measures.

Variation in rolling forces can lead to varying expansion of the stand, compensated for in modern plants by a hydraulic adjusting device (gap adjuster).

In the production of heavy plate for high-strength constructional steels, thermomechanical treatment is increasingly important [188].

In a conventional rolling mill, the output capacity is fully utilized, so that rolling temperatures increase with larger plate thicknesses, but, with thermomechanical treatment, the final rolling temperature is fixed for a given raw material with a predetermined degree of deformation in the final rolling phase [189].

Normalizing forming (also known as high-temperature mechanical treatment, HTMT) is characterized by an end-rolling temperature higher than the recrystallization temperature of austenite. The limitation to the rolling capacity imposed by the cooling phase on the roll table after cogging down must be set against the energy saving due to the lower heating temperatures and the omission of normalizing.

In thermomechanical rolling (low-temperature mechanical treatment, LTMT) the final rolling phase is carried out below the recrystallization temperature of austenite. The considerable increase in recrystallization temperature for this process is achieved by small additions of titanium or niobium, often in combination with vanadium (microalloyed steels). [190]. The necessary lower temperatures of the final rolling, and the high yield strengths of the austenite (which no longer recrystallizes), lead to high stresses on the plant and reduced production rates compared with conventional rolling [191].

The temperature – time characteristics of the three rolling methods are compared in Figure 119. [192].

Figure 119. Temperature – time curves
a) Conventional rolling; b) Normalizing forming; c) Thermomechanical rolling

After the rolled single sheets are cooled on cooling beds, they are usually mechanically cropped or automatically cut by burning to the required dimensions (usually rectangular). The cut edges can be prepared for welding, and the rolled sheet can be supplied in a ready- curved shape.

Figure 120. Design of a hot strip mill [197]
a) Slab-heating furnace (pusher-type heating furnace or walking beam furnace); b) Cogging stands; c) Intermediate roller table with transfer skid; d) Finishing train; e) Cooling roller table; f) Coilers

Depending on the layout of the mills, the rolling program, and the dimensions of the products, heavy plate mills can have outputs of $(0.4-1)\times 10^6$ [193].

Production Process: Hot-Rolled Wide Strip [194], [195]. The raw material used for hot strip rolling is mainly continuously cast slabs, ca. 250 mm thick and, depending on the width, up to 40 t mass, the length being 10 – 12 m. Very rarely, rolled semifinished slabs are used.

The slab is first rolled on one or more reversing cogging stands, producing a semifinished strip, 30 – 50 mm thick. Depending on the width of the hot strip, it may be necessary to reduce the width of the slab in the cogging stands. This "upsetting" of the edges is carried out by vertical rolls, or sometimes by a press.

The semifinished strips are usually rolled on continuous finishing trains to give hot strip ca. 1.5 – 20 mm thick (Fig. 120). Exceptionally, reversing stands are used. For this, the four-high stand is provided with two coilers installed in holding furnaces (Steckel mill) [196]. Strip up to ca. 4 mm thick is the starting material for producing cold-rolled strip. The thicker strip is uncoiled on hot strip cropping lines, and cut into single sheets.

Figure 121. Loop control

The continuous finishing train has 5 – 7 four-high stands whose rotation speeds must be controlled in accordance with the continuity law: cross section × speed = constant. The control parameters can be either the length of strip between two stands (control by looping, Fig. 121), or, for stiff products, the armature currents of the drive motors (minimization of traction force). In the control sequence, the fixed point is the last stand, which has a predetermined constant speed. From this "controlling stand", the entire group of finishing stands is controlled in the reverse direction to that of the rolling operation. This system is also linked to the control of the coiling equipment.

It is essential to maintain a specified final rolling temperature for constant mechanical properties over the length of the strip. As the end of the semifinished strip is rolled in the finishing line some time after the beginning of the strip, it is much cooler, an effect intensified by the water jets used to remove scale. This temperature difference is evened out by the continuous increase in rolling speed over the length of the strip. Final rolling speeds > 15 m/s can be reached, raising the temperature of the strip, owing to the increasing rates of deformation. The final rolling temperature is thus kept constant over the length of the strip.

The variation in temperature along the semifinished strip can also be evened out by means of a coil box. The semifinished strip is formed by bending rollers into a coil on a mandrel or "boom". This is swivelled into the uncoiling position, so that the end of the semifinished strip becomes the beginning of the strip fed into the finishing train [198].

Except for the techniques described above for evening out the thickness differences between the edge and the middle of the strip during hot rolling, an axial shift can be achieved by the use of working rolls, provided with a special profile grinding ability. The hydraulic systems used are known as continuous variable crown (CVC) or universal profile control (UPC) [199], [200].

Because of the variety of materials, precise temperature control is also necessary when coiling the hot strip. This has an important effect on the structure and hence the mechanical properties, which must be suitable for the later treatment processes. This requirement is met by controlling the water rate in the cooling zone, of length 120 – 180 m. Depending on the material, coiling temperatures can be 550 – 780 °C.

After removal from the coiling boom, the coils are mechanically bound, and transferred to the cold rolling mill or to the hot strip finishing shop.

The annual output of hot strip mills can exceed 4×10^6 t, depending on the type of mill and the rolling program.

Since the mid-1980s, the technique of continuous casting thin slabs has enabled hot-rolled wide strip to be produced in considerably smaller production units (Section 3.5.3.11).

Steckel rolling mills have outputs of (400 000 – 700 000 t/a, mostly high-alloy strip (austenites and ferrites) [201].

4.2.2.3. Long Products

Definitions. Long products have a constant cross-sectional area over their whole length, but are usually of variable thickness over the cross section. Long products with a square or rectangular cross section are exceptions to this rule. These have a considerably smaller width/thickness ratio than flat products. Hot-rolled products are usually supplied in standard sizes, to agreed technical specifications. Long products (Figs. 122, 123, 124) include:

1) Wire rod: formed into coils while hot. Nominal diameter or thickness usually > 5 mm. Round, oval, square, rectangular, hexagonal, octagonal, half-round, etc.
2) Bar (solid section): round, rectangular, hexagonal, octagonal, or other shapes. Flat bar of rectangular section, rolled on all four surfaces, thickness > 5 mm, width < 150 mm.
3) Concrete reinforcing or prestressing steel, ribbed or profiled: supplied as bar or wire rod.
4) Permanent way products: rails, sleepers, sleeper clips, fish plates, crane rails, streetcar (tramway) rails (Fig. 122).
5) Sheet piling products: shaped so that continuous walls can be assembled by means of interlocking or clamping devices (Fig. 123).
6) Profiles for mine supports: channel or I-section, with a more pronounced flange taper than with normal I-section (Fig. 124).
7) Large I-section: beams with narrow or medium flanges and web height > 80 mm.
8) Large H-section: beams with broad flanges and web height > 100 mm.
9) Large U-section (channel) with web height > 80 mm.
10) Small I-, H-, and U-section with web height < 80 mm.
11) Angle section: equal-sided or unequal-sided. Rounded edges.
12) Equal-sided T-section.
13) Bulb flat section: flat on one side with a thickened zone on the other.
14) Special sections: usually produced in small amounts.

Equipment for Producing Long Products. Most long products are formed between grooved rolls in two-high or three-high stands. Parallel-flanged beams are produced in universal stands, which can also be used for rolling rails.

Rolling equipment with grooved rolls is characterized by the number of rolls and the roll diameter in millimeters.

The roll passes are the spaces formed between the pairs of rolls by concentric grooves in the roll bodies (Fig. 125). A series of passes, of continuously changing size, to produce the desired final section stepwise, is known as the roll pass design. A system of repeating roll pass shapes (e.g., diamond/square or oval/round) is known as a roll pass sequence.

Figure 125. Roll pass shapes
A) Box groove; B) Diamond groove; C) Square groove; D) Oval groove; E) Swedish groove; F) Round groove

Figure 126. Rolling mills
A) Reversing mill; B) Open mill; C) Continuous mill

The shape of each pass in a roll pass design must be such that a dimensionally accurate product can be rolled, utilizing the flow properties of the material (stretching and spreading) and the available number of roll passes.

The wide range of shapes and sizes of long products requires a large number of roll pass designs, and a wide range of rolling mill layouts. Depending on the production program, this requires a comprehensive stock of rolls, which can include several thousand sets.

The term "rolling mill" includes all the equipment required for rolling the material, and the ancillary equipment for feeding, descaling, edging, guiding, hot cutting, and coiling.

Rolling mills are classified according to

1) The arrangement of the stands and the route taken by the material being rolled (e.g., open or continuous mills)
2) The roll diameter and/or the product (e.g., a 550 mm mill for medium-sized products)

A reversing mill (Fig. 126 A) has one or two stands, through at least one of which the rolling stock passes several times.

In an open mill (Fig. 126 B), several stands are arranged side by side on one axis. These are linked to each other and to the common drive motor by spindles and gears. Two or more strands of steel can be rolled simultaneously in different stands.

In a staggered mill, the stands are arranged with their axes displaced with respect to each other. The rolls can be driven individually, or several stands can have a common drive motor.

In a continuous mill (Fig. 126 C), the stands are arranged in line, so that the strand is rolled in several stands at the same time. For small sections, several strands can be rolled side by side. Depending on the product and/or the material, continuous mills can have horizontal stands only, or alternate horizontal and vertical stands.

Combinations of one or more reversing mills, or an open mill with groups of continuous stands are known as semicontinuous mills.

In continuous mills, the ratio of the rotation speeds of the rolls in the various stands must satisfy the continuity law cross section × speed constant. Deviations give rise to longitudinal forces in the rolled strand, either compression (causing loops), or tension. These forces have a harmful effect on the process and/or the cross section of the rolled product.

Two systems are used to control the longitudinal forces:

Loop control
Control by minimizing tension

In loop control, variation of the size of a loop (a buildup of rolled product between two stands) is used to correct the rotation speed of one of the stands involved. Loop control can be used only for flexible rolled products.

If minimal tension control is used, rolling takes place with only very small longitudinal forces. Physical quantities (rolling forces, rolling torques, and armature currents) are measured and the information is stored before the rolled material enters the next stand; changes in these measured quantities give a measure of the longitudinal forces, and trigger a change in the rotational speed of one of the two stands [202–205].

At the end of the rolling process, the rod-shaped rolled product travels over roll tables to cooling equipment, through which it is moved by various mechanical devices, to give a temperature suitable for processing in the finishing shop.

Finishing operations include straightening and cutting the rod-shaped product, testing for surface and interior defects, marking, and bundling. With some grades of steel, heat treatment is also carried out.

Rolling mills are named according to the size of the section and the mass per meter of long products. They are classified as follows:

Rolling mills for heavy-section products (heavy profile mills and heavy beam mills)
Rolling mills for medium-section products
Light-section and wire-rod rolling mills

The limits in this classification system are not precisely defined.

Rolling Mills for Heavy-Section Products. These mills produce large, heavy, profiled long products, i.e., > ca. 25 kg/m. Products include:

1) Ails
2) Sheet pile
3) Structural steel for mines
4) Beams and channel > ca. 150 mm
5) Bulb plate steel > ca. 180 mm wide

Figure 127. Roll arrangement for making parallel flanged beams
a) Horizontal rollers; b) Vertical rollers

Heavy rolling mills can produce 300 000 – 800 000 t/a. They usually have a cogging or breakdown stand, and, depending on the plant production program, two- or three-high stands, and/or universal stands.

Two- or three-high stands, in which the metal is enclosed and formed by only two rolls are not suitable for rolling parallel flange beams, owing to flow of the metal and wear of the grooves; these products are rolled on universal stands (Fig. 127).

The raw materials for heavy-section rolling mills include:

1) Ingots cast in steelworks
2) Blooms and slabs produced by continuous casting
3) Continuously cast slabs divided longitudinally
4) Rolled or continuously cast rough profiles (dog bones)

The mass of metal is 3 – 10 t, depending on the product and the rolling program. Continuous casting is becoming increasingly important, owing to the higher yield and better surface.

The ingots are heated to ca. 1300 °C, and rolled on a blooming stand to produce a square or rectangular section, or, in the case of broad-flanged beams or sheet pile, to give a roughly profiled product. The rolls of the blooming stand have diameter ca. 1000 – 1200 mm, and are provided with several box-shaped grooves. By screwing down the top roll and turning over (edging) the rolling stock, square or rectangular sections can be rolled in these grooves.

The final section is formed in 7 – 11 shaping passes. Two to four stands are needed, depending on the width of the rollers and the width of the stock being rolled. Roll diameters are 750 – 950 mm. An example of this type of shaping process is shown in Figure 128, which shows the grooves in two stands for rolling rails, the first stand having seven different grooves for seven passes, while the second is designed for four passes, with two grooves being used for each of the last three passes [233].

For parallel-flanged beams, the cogging stand first produces a rough profile, similar to the section produced by the first pass of the subsequent universal mill. Shaping continues in this main stand and a flange-edging stand.

Universal stands have two pairs of rolls, horinzontal and vertical. The web is formed by the driven horizontal rolls, and the flanges by idle vertical rolls. Both pairs of rolls are adjustable,

Figure 128. Roll pass design for making rails

so that the thickness of the web and flanges is reduced at each pass. The dimensional accuracy of the flange edges, which are stretched without restriction, is adjusted by passing through a flange-edging stand.

Figure 129. Reversing tandem group for rolling parallel-flanged beams

Forming can also be carried out in a reversing tandem group. This consists of two universal stands with an intermediate flange-edging stand (Fig. 129).

Universal beam rolling mills are operated as single-purpose mills, but can also be operated as open trains, with the stands arranged parallel to each other, and with a common cogging stand [207].

The plant can be designed as a combined rolling mill (Fig. 130), where complete stands can be removed from the rolling line by changeover equipment. Universal and two-high stands can be interchanged. This gives great flexibility in the rolling program, with rapid changeover [208].

Thermomechanical treatment of rolled steel products is mainly used for beams intended for high-stress applications. The temperature

Figure 130. Operating system in a combined profile rolling mill
A) For beams; B) For other sections

changes during a thermomechanical rolling operation are shown in Figure 131, and compared with conventional rolling. Special attention must be paid to the differences in wall thickness. The thinner webs and thicker flanges can form different structures, owing to temperature differences, resulting in differences in mechanical properties across the section. To limit these temperature differences, the rolled product is selectively water- cooled in the area of the transition zone from the flange to the web. A high degree of low-temperature deformation is required, but limits are imposed by the mechanical loads that the rolls and stands can support [209], [210].

Figure 131. Temperature changes while rolling beams

Another current development is to combine thermomechanical rolling with heat treatment of the rolled product after the last forming pass. This is known as the quenching and self-tempering (QST) process, and consists of rapidly cooling the rolled profile with water. This quenching is interrupted when the interior of the rolled product is still hot enough to reheat the surface region to ca. 600 °C, producing a structure which gives the product a high yield strength and good toughness properties [211].

The finished rolled products can be 60 – 120 m long. They pass over roller tables to the cooling bed which cools them to < 100 °C. Most products can go to the despatch store after normal finishing operations.

Rails undergo extensive quality control and further treatment where necessary:

1) Testing for inner and surface defects
2) Testing for smoothness and straightness
3) Straightening the rail ends
4) Sawing to an exact right angle and very close length tolerances

For special requirements, the rail head can be tempered. This utilizes either the heat from the rolling, or involves an induction heating step [212].

Rolling Mills for Medium-Section Products. Medium-section long products, of less mass per unit length, are linked to the production program of heavy-section mills. They include the following:

1) I-beams with web width 80 – 240 mm
2) H-beams with web width 100 – 240 mm
3) U-section (channel) with web width 80 – 240 mm
4) Equal-sided angle steel, 70 – 150 mm
5) Unequal-sided angle steel, from 60×40 mm to 150×100 mm
6) T-section: 50 – 150 mm
7) Round bar: 40 – 180 mm
8) Flat bar: 80 – 150 mm×5 – 50 mm

The rolling programs for medium-section mills include, in addition to the normal I- and U-sections light structural sections with web or flange thickness ca. 3 mm, and considerably smaller flange width than those of normal sections. These thin-walled products are known as "junior beams" and "junior channels", with web width 6 – 12 inches.

The rolling programs of medium-section product mills are often restricted to certain products, as the production of medium-section products requires plant and rolling techniques that differ in some respects. The main emphasis lies on the production of profiled sections, especially parallel-flanged beams. The products have mass 6 – 25 kg/m, but larger broad-flanged beams lie outside this ange [213].

The raw materials are rolled semifinished products made from ingots or continuously cast blooms of square or rectangular section; weighing 1 – 5 t continually cast blooms are also used.

Apart from plants designed for rolling special products in small batch sizes, e.g., special sections or high-alloy steel round bar, most rolling mills for medium-section products are designed for semicontinuous operation; there are one or two reversing cogging stands and a group of continuous stands. The material that goes to the finishing group, which consists of at least 6 stands, is first rolled on the cogging stand(s) in 3 – 8 passes. The rolls of the two-high continuous stands have diameters 650 – 450 mm.

Continuous trains give shorter throughput times compared with reversing mills, so temperature losses of the rolled products are lower. This ensures that the final rolling temperatures are high enough in the case of small and/or thin-walled profiles, which cool more quickly. When continuous finishing stands are used in conjunction with a crank-cutting device after the last rolling stand, long strands can be rolled and cut as they pass through the stands, improving output and yield. If parallel-flanged beams are included in the rolling program, it is best to have combined two-high/universal stands and flange edging stands. Figure 132 shows a plan of a typical rolling mill for medium-section steel products.

Rolling speeds are 8 – 12 m/s. The rolled strand is cut into optimized lengths, which can be > 100 m, depending on the dimensions of the cooling bed. They are then straightened in machines that can sometimes handle several strands, and passed to the finishing shop.

The outputs of rolling mills for medium-section products, depending on plant design and rolling program, are 250 000 – 800 000 t/a.

Rolling Mills for Light-Section Steel and Wire Rod. Light-section steel comprises rolled products in the form of bar, ca. 12 kg/m. The various sections and dimensions are:

1) Round bar: 8 – 40 mm
2) Square bar: 10 – 40 mm
3) Hexagonal bar: 10 – 35 mm
4) Flat bar: 20 – 80 mm × 4 – 15 mm
5) Angle steel: 20 × 20 mm to 60 × 60 mm
6) T-section steel: 20 – 50 mm
7) U-section steel (channel): 30 – 50 mm

Larger sections are produced by some manufacturers. Most products have solid sections (round, square, hexagonal, and flat); production of profiled-section products (angle, T, and channel section) is not described here.

Wire rod differs from bar in that it is formed into coils after rolling; the production process is very similar for both, so combined wire rod/bar mills are often operated. Light-section steel and wire rod form the largest proportion of hot-rolled long products. The raw material is mainly square section semifinished product with edges 100 – 150 mm long. This can be rolled either from ingots or continuously cast blooms. In the upper size ranges, material can be used direct from the continuous casting machine. The blooms weigh from a few hundred kilograms to > 2000 kg, and are heated to 1150 – 1200 °C.

The stands used for light-section steel and wire rod are arranged for semicontinuous or continuous operation. Open trains are less often used.

Instead of conventional cogging stands, high-reduction machines of various designs can be used. In one pass, these produce a stretching degree of 3 – 10, compared with 1.2 – 1.4 in conventional rolling mills [214].

For light-section products, 10 – 24 rolls passes are required, depending on the raw material and final section; for wire rod, up to 30 passes.

The diameters of the rolls are ca. 550 mm for the cogging stands, ca. 280 mm for the finishing stands. Various roll pass sequences are used for forming (diamond/square, diamond/diamond, oval/round). The thickness of the rolled steel is reduced along each axis of the section alternately; for continuous rolling in horizontal stands, the rolled strand must be twisted after each pass. The twisting operation is often avoided by the use of alternately horizontal and vertical stands (H – V mills). This twist-free rolling method, beginning at an early stage of the rolling process, is preferred for products with high-quality surfaces.

Light-section steel mills can be designed for one or two strands, wire rod mills up to four. Multistrand rolling is only possible with horizontal stands. For improved surface quality and dimensional accuracy of the product, the finishing stands, and even the intermediate stands, are divided into several parallel lines rolling single strands. In light-section mills for round and hexagonal bar, twist-free roll blocks, described in more detail below, are used for the intermediate and finishing trains.

If thermomechanical treatment is to be carried out, it must be taken into account that in continuous rolling mills the final forming operation takes place at high speed, and the distances between the stands are short. This leads to heating of the rolled product. The temperature before the final pass can be reduced to < 800 °C by a water-cooling and equilibration stage after the intermediate rolls, sometimes accompanied by

Figure 132. Plan of a rolling mill for medium-section products
U/H = combined universal/horizontal stand; E = edging stand.

reducing the temperature at which the material leaves the furnace to ca. 950 °C.

The flow rate of the cooling medium is designed to give as uniform a temperature profile as possible, and depends on the section of the product and its composition. Water cooling in the finishing roll block may also be necessary to control the final temperature [215].

The light-section steel leaves the final stand at speeds of 10 – 20 m/s, corresponding with the cycle time for the delivery of the bar or rod to the cooling bed. While the strand is in motion, it is cut with rotary shears into lengths suitable for the cooling bed, preferably of the rake type. For some special requirements, e.g., for certain concrete reinforcing products, the bars can be quenched and tempered using the rolling heat of the material.

In light-section rolling mills, the products undergo the normal finishing processes, according to the material and its intended use.

Significant improvements have been made in the technology of rolling wire rod. These include the development of twist-free roll blocks, and cooling equipment that provides accelerated or retarded cooling. For a wire rod 5.5 mm diameter, the final rolling speed has been increased from ca. 40 m/s in 1960 to > 100 m/s.

Hence, larger cross sections of continuously cast material can be used for the initial pass, without leading to an unacceptably low rolling speed in the first stand. This also enables the coil weight to be increased from 600 to 2000 kg or more [216], [217].

In twist-free roll blocks, up to 10 rolling units are arranged on a single common frame, and these are linked by a system of gears [218]. Forming can be carried out by two rolling disks with an oval/round roller pass sequence (Fig. 133), or by three rolling disks (Fig. 134 A) with the roll pass design shown in Figure 134 B [219], [220].

Figure 133. Two-disk roll block (drive mechanism)

Figure 134. Three-disk roll block
A) Drive mechanism; B) Roll pass design

The disk rolls are made of highly wear-resistant hard metal and give the best possible surface finish. Roll blocks replace conventional roll stands in the finishing trains, and sometimes also in the intermediate trains. The high strand rates obtainable with roll blocks make it possible to replace multiple-strand train by stands with one or two strands.

Experience with roll blocks has enabled so-called precision roll units to be developed. These give improved dimensional accuracy, and are used in both light-section steel and wire rod mills [221].

Wire rod of diameter ca. 5 – 20 mm passes through a water- cooling zone after leaving the last stand. This consists of cooling boxes with intermediate zones to equalize the temperature between the interior and exterior of the product. Finally, the wire rod is formed into loops by a winding head, and these are spread out on a speed-regulated conveyor belt. The overlapping loops are force cooled by a controlled air flow in several zones. Cooling of the wire rod can be retarded by covering the conveyor belt. At the end of the cooling process, the wire loops are collected in coil-forming chambers, and tied into coils (Fig. 135) [222].

With this controlled cooling by water and air, the crystalline structure and condition of the scale are controlled to give the required material properties.

Wire rod of diameter ca. 20 – 40 mm is formed into rings in rotary basket (Garrett) coilers.

Capacities of light-section steel mills are 100 000 – 350 000 t/a, depending on the plant design and the rolling program (dimensions and materials). Multi-strand, high-output wire rod mills can have capacities > 700 000 t/a.

4.2.2.4. Tubes

Steel tubes can be either seamless or with a welded seam, depending on their dimensions and intended use [223]. The current dimensional standard is ISO 4200. The dimensional ranges are fixed partly for technical reasons, but manufacturing costs also play a role. Tables 14 and 15 show how production and export have changed during the last 20 years.

Table 14. World steel tube production, 1000 t

Seamless Tubes. Production of seamless steel tubes is usually carried out in three manufacturing stages [224], [225]:

1) Piercing
2) Elongating
3) Final rolling

In modern plants, one mill is used for each manufacturing stage. In older plants, each stage is usually divided into several smaller stages. The processes are named according to the elongating equipment used. The most important types of plant are:

1) Mandrel mills (Fig. 136),
2) Plug mills (Fig. 137),
3) Push bench mills (with a cross-rolling mill for piercing)

Figure 138. Operating ranges of tube rolling mills

4) Pilger mills

Product size ranges and annual outputs are given in Figure 138.

As well as the four processes, others are used for lower volume products:

1) Assel mills, for ball-bearing tubes and machinery tubes
2) Diescher mills, for medium-sized products, not thin-walled tubes
3) Extrusion presses, for high-alloy materials

Plug and mandrel mills are mainly used for processing unalloyed steels, e.g., simple structural steels, and medium-alloy materials. However, high-alloy steels, e.g., for pipework, oilfield applications, and boiler tubes, are also processed in these mills, the materials 100Cr6, X20CrMoV121, and X20Cr13 being the most difficult materials used.

Raw Materials. The raw material now used all over the world for unalloyed and medium-alloy steels is continuously cast round bar, although continuously cast square bar is also used, either rolled to form round bar, or directly as square bar. Square bar is first pierced by a press piercing mill (integral with the tube production process) to give a thick-walled hollow billet. The cross-sectional area remains approximately constant in this operation. The material for high- chrome steel tubes is still mainly round bar stock, rolled from cast billets.

Pilger mills for large diameter tubes still use cast billets.

Billet Heating. Billet heating is today almost entirely carried out in rotary hearth furnaces. As a rule, these have six zones, and are heated by natural gas or oil, the process being computer controlled [225].

Piercing. By far the most important process for the hole-piercing stage uses inclined rollers. In the method invented in 1886 by the Mannesmann brothers, holes are produced in massive round ingots (Fig. 139) by two inclined rolls rotating in the same direction, so that the ingot is rolled with a screw motion over a piercer plug to form a hollow bloom. The piercer plug is fixed to a freely rotating rod supported by a thrust bearing on the exit side.

In the cross-rolling zone in front of the piercer plug, the core of the material undergoes a continuous transition from compressive to tensile stress, this being caused by the screw motion. If this is too violent, tearing of the core takes place. Formerly, this was thought necessary, but it is now avoided as much as possible by correct design of the rolls, thus preventing interior defects [227–229]. By means of guide shoes

Figure 139. Piercing in a Mannesmann cross-rolling mill
a) Billet; b) Piercer plug; c) Cross-roll; d) Working rolls; e) Supporting roll; f) Guide shoe; g) Hollow bloom

(Stiefel mills, Fig. 140) or disks (Diescher mill, Fig. 141), modern cross-rolling mills are able to produce thin-walled tubes at such a high rate that they can be used, even in high-output plants such as plug and continuous mills [230]. Particularly with plug mills, where the elongating ability of the rolling mill is limited, it was necessary to roll the hollow billet in two stages. In the first cross-rolling mill, a thick-walled hollow billet was produced, and in the second mill the hollow billet was elongated in preparation for the final plug rolling process.

Figure 140. Cross-rolling piercer, Stiefel type
a) Piercer plug; b) Working roll; c) Guides

Elongating. Longitudinal rolling, transverse rolling, or presses are used for the elongating stage. The most important longitudinal methods are:

1) Continuous tube rolling mills
2) Plug mills
3) Push benches
4) Pilger mills

Of these, the continuous tube rolling process is the most important, as it is one of the most efficient and productive processes, and is used for products where the demand is highest. The name expresses the fact that several stands are used simultaneously. There are usually 6 – 8 two-high stands per group, at an angle of 90° to each other. The wall thickness reduction takes place between the rolls and a cylindrical lubricated mandrel (Fig. 142).

There are three types of process:

Type 1. Free-floating mandrel, with stripping of the mandrel as a separate operation
Type 2. Semifloating mandrel, where the mandrel speed is about the same as the exit speed from the first stand, with stripping of the mandrel as a separate operation
Type 3. Semifloating retained mandrel, with short working length (twice the distance between two stands); the rolled product is pulled from the mandrel by pulling equipment, and the rod is pulled back through the rolls to the entry side

For elongating by cross-rolling, the following equipment is used [231]:

1) Diescher mills
2) Assel mills
3) Planetary cross-rolling mills

Cross-rolling processes are used only for plants of small to medium capacity. Owing to certain engineering aspects of the cross-rolling process, thin-walled tubes are difficult or impossible to produce with this type of plant.

A further possibility is to use extrusion presses, but only special materials such as high-alloy steels are processed in this way.

Figure 142. Arrangement of rolls and roll passes in a mandrel mill
a) Rolls; b) Mandrel; c) Clearence

Finishing. Rolling to the finished size is carried out without an inner mandrel in sizing mills or stretch-reducing mills. Sizing mills have 2 – 10 stands, and can have two or three rolls per stand. As the circumference is reduced, the wall thickness is increased by the sizing mill.

In stretch-reducing mills, which normally have three rolls per stand, and up to thirty stands (Fig. 143), an increase in wall thickness is avoided, as tensile forces are applied between the stands during the process.

Figure 143. Stretch-reducing mill
Rolls marked V are shown staggered through 60°.

∗ High-grade steel tubes.

Further Heat Treatment. Tubes for undemanding applications can be shipped immediately after rolling. For more exacting quality requirements, especially good toughness properties, separate heat treatment is usually carried out after rolling. This can include normalizing and tempering. Normalizing mainly improves toughness, and tempering considerably improves both strength and toughness.

Research has been intensified into tempering the product during rolling, i.e., quenching the tube to $< 100\,^{\circ}\mathrm{C}$ after it leaves the final roll pass, having been heated by rolling to temperatures above A_{C3} (A_{C3} is the temperature at which the transformation of ferrite to austenite is complete). The tube then undergoes a further separate heat treatment stage.

Welded Steel Tubes. Welded steel tubes are produced with longitudinal or spiral welds. The starting material is cold- or hot-rolled steel strip, hot-rolled wide strip, or thick plate.

The manufacture of these starting materials involves considerable cost. Therefore, seamless tubes of medium wall thickness and medium diameter are often cheaper to produce than welded tubes, although production of the latter does not present any technical problems. New developments in near net dimension casting may well lead to changes.

The physical properties which the tube should possess are often already present in the rolled raw material. However, changes, especially to the yield strength, caused by the forming operations must be taken into account. A typical example is the thermomechanically rolled thick plate or hot-rolled strip used in the production of large tubes. The finished tubes can also be heat treated or cold hardened.

Figure 144. Fretz – Moon rolling and welding plant viewed from below
a) Heated strip; b) Forming rolls; c) Welding rolls; d) Welded tube

Forming of the flat products into tubes can be carried out hot or cold, as a continuous or batch process.

The welding processes are of two types (Table 16):

Pressure welding processes
Fusion welding processes

Pressure Welding. In the Fretz – Moon process (Fig. 144) coils of hot-rolled strip are heated to a high temperature in a tunnel furnace, and the edges of the strip are heated to welding temper-

ature by additional burners. The strip is formed by rolls into a tube with a longitudinal gap, and a two-roll compression device at 90° then reduces the gap and presses the edges together so they become welded.

The semifinished tube passes without further heating through a stretch-reducing mill, where the dimensions are reduced as required. A flying saw cuts the continuous tube into lengths, which are then cooled on a cooling bed. The welding process is controlled by a hot-tube eddy current device, which monitors the semifinished tube and is located behind the compression equipment. The tubes produced are thin-walled with diameter ca. 21.3 – 114.3 mm.

Figure 145. Conductive high-frequency welding
a) Open-seam tube; b) Gap angle at feed; c) Sliding contacts; d) Welding generator; e) Compression rollers; f) Welding point; g) Weld seam

There are three methods of resistance pressure welding, the most important of which is the high-frequency method introduced in the early 1960s. Here, too, the simultaneous effects of pressure and heat are used to weld together the edges of an open-seam tube into a tube without any added material. The heat is generated by the energy of a high-frequency alternating current, which produces a magnetic field within the conductor, increasing the ohmic resistance. This causes electrons to flow along the edges of the strip to the point where the edges meet. Energy production is greatest at this point, where the approach effect at the counter- conductor occurs.

The welding current can also be carried to the gap by conduction (Fig. 145), with sliding contacts, or by induction, using singly or multiply wound coils. Forming is by shaped rolls or roller cages. The tube outer diameter is 20 – 600 mm, with wall thickness 0.5 – 15 mm. The raw material is coiled steel strip or hot-rolled wide strip. The strip can be pickled or cold rolled, depending on the intended use.

The bulb formed both inside and outside the tube by the pressure welding process is planed or scraped off while it is still hot, and the tube is then rolled in 2 – 6 reducing stands to give a circular section of the correct dimensions. It is possible to form the round tube into a different profile, e.g., square, by profiling stands. Here, too, nondestructive testing of the welded seam is carried out continuously.

The properties of the welded seam can be improved, either by continuous heat treatment to give partial normalization, or by a separate heat treatment of the individual tube.

Fusion Welding. Fusion-welded steel pipes, mainly produced in diameters of > 457.2 mm (18 in), are used in pipeline construction. Four forming processes are used (Fig. 146), the last two being by far the most important. Welding is carried out under a powder, often in combination with tack welding under a protective gas.

In the submerged arc welding process, the electric arc is formed under a layer of slag and powder. The added material is coiled, uncoated welding wire. The welding current is fed to the wire by sliding contacts, and is carried away via the electrically earthed workpiece (Fig. 147).

In the protective gas welding process, the electric arc can be seen, although the electrodes, electric arc, and weld pool are protected from the atmosphere by a stream of inert or active protective gas. The following processes are used:

Tungsten – protective gas welding:
- tungsten – inert gas welding (TIG)
- tungsten – plasma welding (TP)
- tungsten – hydrogen welding (THG)

Metal – protective gas welding:
- metal – inert gas welding (MIG)
- metal – active gas welding (MAG)

The TIG, MIG, and MAG processes are used in tube manufacture.

Cold Working. Some seamless and welded tubes are subjected to cold working. This enables wall thicknesses and cross sections to be produced to better tolerances, improves physi-

Figure 146. Pipe-forming processes

cal properties, and, not least, enables tubes with thinner walls and smaller diameters to be produced.

Figure 147. Submerged arc welding process

Four variations of the cold drawing process are used (Fig. 148). Cold working increases the yield point and hardness of the material.

Figure 148. Cold drawing process
A) Sinking; B) Rod drawing; C) Plug drawing (fixed plug); D) Plug drawing (free plug)

A much greater degree of deformation can be produced by cold treatment with a Pilger mill (Fig. 149) than can be achieved by drawing. The rough tube is elongated over a stationary conical mandrel by two specially shaped rolls. These roll the tube, first in one direction and then the other, in a regular repeating cycle.

Figure 149. Cold rolling in a Pilger mill
a) Roll axis; b) Roll groove; c) Roll; d) Rough tube; e) Mandrel; f) Finished tube

There is a great reduction in diameter and wall thickness, so that any irregularities in the rough tube are effectively eliminated. A tube rolled in a Pilger mill is therefore characterized by close dimensional tolerances and extremely good surface finish.

4.2.3. Forging

4.2.3.1. Open Die Forging

Open die forgings are the products of forging plants, which can operate by compression (presses) or impact (hammers). Advantage is taken of the malleability of steel at high temperatures to produce a wide range of shapes, some very complex, from almost all grades of steel. The importance of these products lies in the fact that, not only are the design requirements of a steel product largely fulfilled by forging and machining, but so also are the quality requirements. This is a result of the improvement in steel quality brought about by forging, and the heat treatment that it entails.

Figure 150. Bronze-clad shaft for a ship's propeller
Material 32CrMo12; Length 7400 mm; Diameter 682 mm; Mass 22.4 t

The amount of crude steel used in open die forging is small compared with the total annual output of steel, but this does not give a true indication of the economic significance of the process. This is only truly reflected if all the stages of value addition are taken into account, starting with the ingot, and finishing with the machined forging, ready for use.

Figure 151. Schematic of a ship's propulsion system with components produced by open die forging
a) Rudder post; b) Propeller shaft; c) Coupling bolts and nuts; d) Intermediate shaft; e) Thrust shaft; f) Gears; g) Pinion shaft; h) Coupling; i) Connecting rod; j) Crankshaft; k) Wheel tire; l) Propeller key; m) Propeller retaining nut; n) Rudder shaft retaining nut; o) Rudder shaft

Customers for these products constitute a highly developed processing industry, with considerable demand potential.

Almost half the products of open die forging go to the mechanical engineering industry. Other consumers include the electrical industry, shipbuilding, diesel engines, mining, quarrying, earthmoving, the heavy chemical industry, structural steel engineering, and the iron and steel industries (Figs. 150 and 151). Smaller consumers are supplied by merchants.

Figure 152. Forging bloom (350 t) in an 80 MN press
Material 26NiCrMo1010; Total length 5300 mm; Diameter 3700 mm

Figure 153. Forging the shaft of a water turbine on a 40 MN press
Material Ck35; Ingot mass 100 t; Forged mass 60 t; Maximum diameter 2010 mm; Total length 6000 mm

The range of steel grades used extends from unalloyed carbon steel, through low- and medium-alloy grades, to high-alloy and stainless steels. The raw shapes used in open die forging include continuously cast steel, semifinished rolled products, and large ingots (Figs. 152 and 153). The largest ingots for forging weigh 650 t (Japan), and, in Europe, 450 t (Germany). Attempts are being made in the People's Republic of China to produce an ingot of 350 t by the electroslag remelting process. The most modern methods of steel production are used to ensure that the starting materials are of the highest possible purity.

The main machines used for hot forming by open die forging include hammers, hydraulic presses (oil or water), and two- or four-hammer forging machines. All types of machine are available in a range of power ratings. The largest are open die forging presses rated at 150 MN (Italy) and 120 MN (People's Republic of China). For environmental reasons, hammers have been increasingly replaced by open die forging presses and forging machines. Ring rollers are machines for hot forming ring-shaped forged products, mentioned here for completeness. The ring roller, with its preheating furnace, upsetting press, and perforating press, form a single unit (Fig. 154).

Figure 154. Ring for rotary ball mill
Material 50CrMo4; Diameter 6000/5600 mm; Height 200 mm; Mass 5.8 t

Open die forging includes both preheating and shaping. Correct preheating is a necessary precondition for economic, problem-free forming. The preheating process used and its duration depend on the size of the forging and the composition of the steel. When forging does not involve the use of shaped tools, experience of working procedures is necessary, including the use of the correct force and power for the shaping operation, and the correct positioning of the workpiece

before each stroke of the hammer. The forming properties of a particular material depend on the nature of the material, its temperature, and the rate and extent of deformation.

The procedures used with power-driven hammers and presses, between flat or profiled saddles are the same as those used in hand forging on an anvil. A forging can sometimes be completed in one working cycle, but usually the final form is obtained gradually, after several different types of working procedure.

Forging always brings about an improvement in the structure of the raw ingot; it tends to remove defects in the ingot which were produced during manufacture, the properties being improved in all three directions. An ingot of given dimensions is given a smaller or larger cross section, i.e., it is stretched or upset. The quality of a forging is determined not only by the type and purity of the steel and its subsequent heat treatment, but also by its drawing-out ratio (initial section : final section). The fiber orientation in a forging should conform to the stresses that the forging will receive in use.

After forging, the workpiece is cooled. Depending on the grade of steel and the dimensions of the forging, this is carried out in still air, under matting, ashes or coarse sand, or in pits or furnaces. For larger forgings and special grades, heat treatment may be necessary before cooling to remove any exterior and interior cracks, giving a product that will pass an ultrasonic test. A crack-free exterior depends on the state of stress in that area, and a crack-free interior depends on effective diffusion of hydrogen, the state of stress, and the structure. A good ultrasonic test result depends on grain refining in the forming process.

Tempering in the unfinished state, i.e., before machining, is carried out, with the aim of producing particular properties (technical parameters, tensile stresses, etc.). Tempering consists of two heat treatment steps: hardening and stress relief. In addition to special equipment for thermochemical treatment to modify the surface down to various depths, equipment is available for heat treating forgings, e.g., vertical, shaft, and horizontal (bogie hearth) furnaces, and heated or unheated pits. Hardening is carried out in still air, by ventilators or compressed air, by dipping in oil or water, or by spraying with water or water – air mixtures.

Machining workshops are often located in the vicinity of the open die forging plant; the end user is often not equipped to machine workpieces to conform with the design drawing. Workpieces must be machined before the final heat treatment, depending on the grade of steel (Fig. 155). For these reasons, a link between the forging plant and the machining workshop has developed.

Figure 155. Generator shaft for the largest hydroelectric power station in Norway
Material Ck35; Mass 97.2 t; Ingot mass 270 t; Body diameter 2256 mm; Total shaft length 9390 mm

4.2.3.2. Closed Die Forging

History. Closed die forging is a very old process for producing identical parts. Its importance increased greatly after the invention of the steam engine. This provided the energy necessary for the closed die forging of steel (steam-driven hammers), and enabled large numbers of similar forgings to be produced.

Closed die forging is a highly developed area of industry. The countries that produce the most steel products by this technique are Japan, Germany, the United States/Canada. Each of these produces ca. 10^6 t/a; the other countries of Western Europe produce a further 10^6 t/a.

Definition. In closed die forging, the die is a block of steel, usually rectilinear, in which the "negative" shape (known as the impression) of the article that is to be produced has been machined.

The die usually consists of two halves, between which the slug that is to be forged is placed.

The two halves of the die are then closed by impact or by a press.

Closed die forging is thus a massive forming process, at the end of which the workpiece is completely enclosed by the forming tool. This differs from open die forging, in which the tool does not have the shape of the forging, or only to a limited extent, the workpiece being produced by relative movement between the tools and the slug.

Raw Materials. All metals capable of plastic deformation, including nonferrous metals and steel, can be forged, e.g., in a die.

Steel is the most frequently used material in the production of closed die forgings. The designer has a large number of standard grades of steel from which to choose the most suitable material for a particular requirement. These include ordinary mild steels, tempering steels, stainless steels, or special alloys based on nickel and cobalt (poor forming properties requiring large forces).

The starting materials for die forging are usually rolled billets (square section), bars, and flats. Billets and bars are cut into slugs, and flats are cut into cropped pieces. Slugs and cropped pieces are the raw materials for closed die forging.

Before the forging process, the raw material is heated in fuel-fired batch type, rotary-hearth, or continuous furnaces, or electric heating machines (induction or conduction), to 1100 – 1200 °C.

The material is heated to reduce its deformation stress. Hot, warm, and cold forming can be carried out, but the deformation stress is greater in the last two processes. The tools and machines available limit the degree of deformation achievable, and hence the possible range of die-forged workpieces. Both cold and warm processes give improved accuracy, but the most important process today is hot die forming.

Tools. Because the die is expensive and product specific, closed die forging is, with few exceptions, economic only for a large number of forgings.

The materials used to make the dies are mainly hot-work tool steels, which retain their strength at high temperatures. This is very important when the steel, heated to ca. 1200 °C, flows in the die impression and heats its surface.

Tool life is determined by the wear caused by flow of the raw material and stresses due to heat and pressure; it is defined as the number of forgings that can be produced before the die becomes unusable, and depends on the die wear that still gives acceptable dimensional tolerances in the forging.

The die impressions are produced by machining (turning or milling), or by spark erosion.

A large range of methods of surface treatment are used to improve the wear resistance of the die surface, and hence to increase tool life. The best known include nitriding and metal deposition by welding. Laser alloying processes have shown promise.

Forming Machines. Steel die forgings are produced with the aid of hammers (drop hammers, double-acting hammers, counterblow hammers), presses (crank presses, eccentric presses, screw presses), horizontal forging (upsetting) machines, and other special forging machines. All have their advantages, disadvantages, and special areas of use. Most forged articles can be produced with either hammers or presses.

Hammers and screw presses (fixed energy machines) differ from ordinary presses (fixed movement machines) in that the former involve successive blows of the ram onto the metal in the die, whereas, in the case of a press, the ram header has a fixed lower reversing point, and the forming process in the die must be terminated by one header stroke of the ram header. The ram of the hammer is traveling at its greatest velocity when it first strikes the metal slug, whereas the ram header of the press has a much lower velocity at this point. These different velocities lead to different deformation stresses of the metal being formed, so that a greater amount of deformation can be achieved by one header stroke of the ram header of a press than by one blow of the ram of a hammer, for machines of comparable size.

Forming Process. The forming of a cropped billet to give a finished forging can take place in one or more stages; the choice depends on several factors.

Edging of the material may be necessary as a first step if the forging to be produced has large

changes in section, or if a specific fiber orientation of the material in the forged item is required; this process may involve upsetting, stretching, or automatic roll stretching. If the raw material is a flat, the distribution of the material is determined by the shape of the cropped piece.

A preforming step is used if the work of deformation during production of a complex forging is too great for a single operation, or if the metal flow in the tool takes place so rapidly that forging defects are produced. It can also be used for economic reasons; preforming dies cost less than finishing dies, and the smaller amount of flow or material in the latter leads to a longer die life.

The final forming step is carried out in the finishing die, which has the shape of the forging being produced, but with the dimensions increased by the amount that the forging shrinks on cooling.

These forming operations can be carried out in various machines, but if no special machinery, e.g., forging roll, is necessary, they are carried out alongside each other in the main forging plant. The finished forging has a flash that must be clipped. Flash-free forging is possible, but there must be exactly the right amount of starting material in, e.g., the slug, as fluctuations in the mass can lead to variable thicknesses of the forgings. When forgings are produced with a flash these variations are mostly compensated by the flash.

After flash removal, the forging is often warm calibrated to achieve closer tolerances. The tolerances of particular parts of the forging may be further improved by a cold calibration of these parts.

Heat Treatment. The properties of the steel are usually improved by heat treatment of the forging. This can involve normalizing or quenching and tempering utilizing the heat present in the forging, or, for some grades of steel, using controlled cooling of the hot forging, so that the required mechanical properties, e.g., tensile strength, yield point, or notched bar impact test figures are achieved. The machinability of the forging can also be affected by its structure.

Dimensional Accuracy. The dimensional accuracy achievable depends on the particular forging and the degree of sophistication of the production methods. Dimensional tolerances and permitted deviations are standardized in most countries. In Western Europe, values are harmonized to conform to a Euroforge proposal of 1965. These standards are rather complex, as the rules apply to some 100 000 different types of forgings. The standards quote two quality levels, one for normal manufacture, and one for more sophisticated production methods.

It is possible to produce better dimensional accuracy than that given in the standards. The products are then known as exact forgings, or, with even better tolerances, precision forgings.

Die forgings are normally machined, at least on their functional surfaces. Machining allowances are therefore specified.

Very close dimensional tolerances, which involve high manufacturing costs, are normally only demanded if the cost of machining can be avoided as a result. The decisive factor is the cost effectiveness of the finished die forging.

Shapes and Uses of Forgings. It is estimated that ca. 600 000 different kinds of forgings are produced worldwide, differing in shape and size, and amounting to millions of items.

The range of forgings produced by hammering and pressing in two-part dies can be considerably extended by further forming in upsetting machines, or by a combination of forging and welding.

Closed die forgings can range in mass from a few grams to well over 1 t.

The main consumers of die forgings include the motor vehicle industry (ca. 70 %) and the engineering, mining, railway, shipbuilding, and aircraft industries.

4.3. Cold Rolling

4.3.1. Introduction

For many applications, the products of hot rolling are unsatisfactory, e.g., with respect to cross section, surface quality, dimensional accuracy, and general finish, so that cold rolling is necessary, i.e., reduction of the thickness of the hot-rolled strip between two working rolls without additional heating. Cold rolling of steel is mainly used in the production of light-section,

thin sheet, and stainless steel sheet of thickness 0.1 – 3.0 mm.

The production cycles in a cold rolling mill differ considerably from those in a hot rolling mill. The raw material is first descaled, rolled, and then heated. Further steps are slitting, coiling, inspection, skin-pass rolling and packing.

4.3.2. Pickling

Hot-rolled steel sheet always has a layer of scale of variable structure on its surface, depending on the hot rolling conditions (Fig. 156). The method of descaling depends on the composition of the scale. For high-grade steels, chemical descaling is carried out in hydrochloric or sulfuric acid, while stainless steels are normally pickled in a nitric acid mixture. Purely chemical descaling is often a long process, but it can be accelerated by preliminary mechanical descaling, e.g., stretching, leveling abrasive blasting, or rolling. Effective descaling requires the scale to be broken down.

Figure 156. Structure of the scale layer on hot-rolled unalloyed or low-alloy steel
A) Coil temperature ca. 570 °C; B) Coil temperature ca. 750 °C

Pickling is carried out in continuously operating plants (Fig. 157). There are usually two payoff reels from which the strip is run. It is first cut by cropping shears to form the beginnings and ends of the strips, and the start of the band is machine welded to the end of the previous band. Great care must be taken in the production of the weld bead, as this is rolled in the cold rolling mill, and must not be torn off. So that the actual pickling process can take place continuously during this interruption to the flow, there is a storage looper between the welding machine and the pickling plant. After welding, the storage looper is refilled at ca. 2.5 times the pickling speed.

Before the actual pickling process, there is usually a stretcher – bend – leveling device which also causes mechanical descaling. This preliminary descaling is very important, as there must be a certain percentage of free iron surface in the pickling bath, so that pickling can start. Normal steels are usually pickled in 20 – 25 % sulfuric acid at 95 – 100 °C, or 15 – 20 % hydrochloric acid at 60 – 70 °C in three or four fully enclosed pickling baths. For strip speed 240 m/min, the dwell time in the bath is ca. 20 – 30 s. The pickling time depends not only on the steel composition and hot rolling conditions, but is also a function of acid concentration, temperature, and concentration of iron(II) salt, which increases as the dissolution of scale proceeds.

The chemical reactions during pickling are described in the literature [232–236]. Individual pickling reactions are given in Table 17.

Table 17. Pickling reactions

$Fe_2O_3 + Fe + 3\,H_2SO_4$	$\longrightarrow$	$3\,FeSO_4 + 3\,H_2O$
$Fe_3O_4 + Fe + 4\,H_2SO_4$	$\longrightarrow$	$4\,FeSO_4 + 4\,H_2O$
$FeO + H_2SO_4$	$\longrightarrow$	$FeSO_4 + H_2O$
$Fe + H_2SO_4$	$\longrightarrow$	$FeSO_4 + H_2$
$Fe_2O_3 + Fe + 6\,HCl$	$\longrightarrow$	$3\,FeCl_2 + 3\,H_2O$
$Fe_2O_4 + Fe + 8\,HCl$	$\longrightarrow$	$4\,FeCl_2 + 4\,H_2O$
$FeO + 2\,HCl$	$\longrightarrow$	$FeCl_2 + H_2O$
$Fe + 2\,HCl$	$\longrightarrow$	$FeCl_2 + H_2$

As the area of the clean steel surface increases, the pickling time decreases until a point known as the critical free surface is reached. For hydrochloric acid, this is ca. 15 %, and for sulfuric acid, ca. 2 %.

After leaving the acid baths, the strip is washed, dried, oiled, and coiled to form rolls of the required mass. The storage looper compensates for interruptions to the process. All pickling plants are provided with trimming shears,

Figure 157. Continuous pickling plant
a) Cropping shears 1 (head); b) Welding/planing machine; c) Cropping shears 2 (foot); d) Stretch – bend – leveling device; e) Pickling/washing; f) Stamping device; g) Trimming shears; h) Cropping shears; i) Take-up reel; j) Exit looper 2; k) Entry looper; l) Pay-off reel

normally located at the exit, though in some plants at the inlet.

The used acid can be regenerated, in the case of sulfuric acid by precipitating iron sulfate as its heptahydrate in a crystallizer.

Hydrochloric acid can be regenerated by decomposing the iron chloride to hydrochloric acid and iron oxide, by a spray process at 450 °C, or in a fluidized bed at 850 °C [237].

4.3.3. Rolling

After pickling, the descaled hot-rolled strip is cold rolled, reducing its thickness (1.5 – 5 mm) by up to 90 %. Many types of stands are used in the production of cold-rolled strip, e.g., two-high, four-high, or larger. In reversing stands, one roll pass can be immediately followed by another by reversing the direction of the rollers. Reversing stands with many rolls exert a high pressure on the strip because the diameters of the working rolls are small. These stands are therefore mainly used for steels with work-hardening properties, e.g., stainless steels and electric sheet steels.

Some 4 – 6 four-high stands can be installed one after the other to form a so- called tandem cold rolling mill (Fig. 158). These mills have the advantage that the strip reaches its final thickness by going in one pass from the pay-off reel through all the stands. Strip speeds at the exit can reach 2400 m/min.

The gap is lubricated with an oil – water emulsion to enable a high degree of deformation (thickness reduction) to be achieved at high rolling speeds. The oil provides lubrication, and the water absorbs the heat produced in the rolling process.

The most important types of cold rolling stands are shown in Figure 159. Areas of use are a function of the work-hardening and thickness of the product strip. Working rolls with small diameters can bend in a horizontal plane, and this can affect the profile; they are therefore given side support in many types of stand.

Experiments have shown that it is not possible to change the profile in a cold rolling mill, so the hot-rolled strip profile must be produced to close tolerances. If the shape of the gap between the rolls does not correspond to the profile of the strip being rolled, flatness defects can occur (differences in the length of individual fibers) [238].

The control elements usually used to adjust the flatness are:

1) Curved working rolls, both positively and negatively. Gap correction up to 180 µm can be achieved.
2) Adjustable intermediate rolls. This system requires six stands.
3) Thermal changes to the crowning of the roll. The degree of thermal expansion of the roll body can be changed locally by adjusting the cooling, but this can only produce extremely small changes.
4) Continuously variable crown systems (universal profile control). The rolls can be adjusted to produce a convex or concave gap; the range of control here is ca. 400 µm.

With the aid of precisely controlled strip tensions between the stands and highly developed measuring and automation technology, it is possible to provide a gap shape appropriate for the shape of the strip. With this system, flat cold-rolled strip with thickness variations of only a

Figure 158. Six-stand tandem cold rolling mill

Figure 159. Types of cold rolling stand

few thousandths of a millimeter and high-quality surface finish can be produced.

Cold rolling causes work-hardening of the steel. This is reduced by an annealing stage.

4.3.4. Annealing

The cold-rolled coiled strip is stacked in a hood furnace for annealing (Fig. 160). The combustion chamber is heated by oil or gas burners. The heat passes through the protective hood into the space where the steel coils are stacked. A circulating fan provides as uniform a temperature distribution as possible. The atmosphere in conventional plants is usually HNX gas (a nitrogen – hydrogen mixture in which the hydrogen content is close to the flammability limit).

The heat passes into the coils through their outer edges, so that these areas are always hotter than the inner windings, especially during heating up.

This heat treatment causes the organic residues of the emulsion to burn off without leaving a residue, in accordance with the reactions given in Table 18 [239–241]. The strip is then heated to the recrystallization temperature, and annealed under the protective gas at ca. 700 °C. This treatment produces a complete recrystallization of the cold-rolled steel. The coils are cooled by removing the outer casing. As the annealing space is then hotter than its surroundings, heat passes out of the protective hood in the reverse direction. The outer windings of the coil cool more quickly than the inner windings. If the cooling is too rapid, tensions due to shrink-

Figure 160. Hood furnace with heat transfer and gas flow indicated

ing occur, and these can cause diffusion welding of the windings (stickers).

Figure 161. Comparison of annealing times in a hood furnace under HNX and H_2 atmospheres

Table 18. Annealing reactions

$CO_2 + C$	$\rightleftharpoons$	$2\,CO$	Boudouard reaction
$CO + H_2O$	$\rightleftharpoons$	$CO_2 + H_2$	Water gas reaction
$Fe + x\,CO_2$	$\rightleftharpoons$	$FeO_x + x\,CO_2$	Oxidation of iron due to CO_2/CO ratio
$Fe + x\,H_2O$	$\rightleftharpoons$	$FeO_x + x\,H_2$	Oxidation of iron due to H_2O/H_2 ratio
$C + 2\,H_2$	$\rightleftharpoons$	CH_4	Methane reaction

Annealing in this type of furnace was formerly very slow. Another serious limitation was the limited rate of cooling attainable, so that certain grades of steel were very difficult to produce in this furnace. An annealing process in a 100 % hydrogen atmosphere with improved convection has been developed more recently. This gives shorter annealing times (mainly owing to the rapid cooling), and more uniform mechani-

Figure 162. Continuous annealing plant

cal properties. The hydrogen easily diffuses into the coil windings, and its conductivity is a factor of seven greater. Moreover, the smaller H_2 molecules enable more rapid circulation of the atmosphere (high convection, Fig. 161).

The continuous strip annealing process was developed in Japan in the 1970s (Fig. 162). At the feed end there are: a double-feeder pay-off reel, a welding machine, a cleaning zone, and a storage looper (required if coils need to be welded together to give continuous operation). The strip then passes through the heat treatment zone: heating chamber, annealing chamber, cooling unit, tempering zone, and second cooling chamber. These are followed by the exit looper, the skin pass mill, the side-cutting shears, the inspection area, the cut-to-length line, and the double-coiling reel. As the treatment time for the material is short (ca. 10 min), the annealing temperature is higher than in the batch annealing process.

Figure 163. Heating cycles of continuous annealing

There are four continuous annealing processes which compete worldwide, differing mainly in the cooling equipment used, and the cooling rates achieved [242].

The recrystallizing annealing process eliminates the hardening produced by cold working, but the mechanical properties of the annealed strip are poor: low tensile strength, low yield point, high fracture strain, etc. Annealed thin strip has a marked upper yield point and a large extension at the lower yield point.

There are two basically different annealing cycles for continuous annealing furnaces (Fig. 163). In the first, the strip is heated to the annealing temperature, held at this temperature, cooled to the dwell temperature, held again, and then cooled to room temperature. The other alternative consists of heating to the annealing temperature, cooling with gas jets to an intermediate temperature, and quenching in water to room temperature. The strip is then brought up to the aging temperature, and finally cooled again to room temperature. Treatment at the aging temperature is not necessary for dual-phase steels.

Various steel grades can be produced in these two annealing cycles.

Quenching is produced by the rapid cooling of the strip in the continuous annealing process, so that the carbon remains in solution. For this reason, continuous annealing is very suitable for producing high-strength, dual-phase, and IF (interstitial-free) steels.

4.3.5. Skin-Pass Rolling

As stated above, the annealed material must be rolled (skin-pass rolling) to prevent flow lines owing to the distinct upper and lower yield points. This also produces the roughness which customers require. This is of great importance for deep drawing or coating the steel. For example, if complex deep-drawn parts are required, e.g., for automobile construction, the surface of the steel should be rough in order to retain the lubricant. Good coating properties require a surface with a large number of peaks, which should be randomly distributed.

4.3.6. Stainless Steels

The processing of stainless steel in a cold rolling mill is quite different (Fig. 164). Austenitic stainless steel behaves differently from ferritic stainless steel. The hot-rolled strip is first annealed. This is necessary because, after the hot rolling process, the strip cools slowly, and carbon tends to precipitate at the grain boundaries,

owing to its reduced solubility at lower temperature. Annealing causes the carbon to go back into solution. Rapid cooling of the strip then prevents the carbon from precipitation by diffusion. Although the annealing time required to bring the carbon into solution is short for austenite, a long time is necessary for ferritic steels, so that batch annealing is necessary. In the continuous furnace, annealing is carried out in an oxidizing atmosphere to produce a scale with a high oxygen content, thereby assisting the pickling process. This does not apply to high-grade steels. The strip is then quenched, by air – water cooling.

Annealing in the hood furnace is successful because of the increase in throughput obtainable under the reducing atmosphere. Considerable increases in throughput have been achieved by the use of hydrogen, even though its concentration is only 25 %.

A high proportion of the scale is removed by abrasive blasting. Although the abrasive particles are mainly spheroidal, a high degree of roughness is produced. This must be removed by rolling, another cause of the high deformation strain in high-grade steel mills.

Sodium sulfate is used in electrolytic pickling. The electrolytic pickle liquor is in effect self-regenerating.

Conventional pickling is carried out with a mixture of nitric (12 – 14 %) and hydrofluoric acid (2 – 4 %). Pickling temperatures are usually 40 – 60 °C. Unlike sulfuric acid or hydrochloric acid pickling solutions, regeneration is not possible, so that the spent acids must be rendered harmless and disposed off.

After pickling, the strip is usually rolled on "Sendzimir" rolling mills (more rarely on four- and six-high stands).

The strip is then annealed to convert the steel from the work-hardened state produced by cold rolling into a recrystallized and stress-relieved state, to enable further treatment of the strip to be carried out.

Stainless steels are to an increasing extent being annealed in bright annealing plants [243], as this process enables the bright surface produced by cold rolling, and typical of special steels, to be retained (Fig. 165).

The strip is finally rolled again (skin-pass rolling).

4.3.7. Future Developments

The extent of automation in cold rolling mills has raised the possibility of linking the individual process steps. For instance, attempts are being made to link the pickling stage with the tandem rolling operation. This requires the outputs of the two operations to match. In Japan, a cold rolling mill is being operated in which pickling, rolling, and continuous annealing have been combined, despite the fact that the outputs of the continuous annealing process and the rolling mill do not correspond. The maximum economic output of a continuous annealing plant is 800 000 t/a in the late 1980s, while tandem rolling mills can easily achieve twice this production rate.

5. Surface Coating

5.1. Introduction

Technical developments have greatly increased the output of surface- coated steel strip. The demand for improved corrosion protection is not the only driving force. The properties of coated strip, such as the yield point, expansion properties, and cold workability needed to be improved before these products could be used, e.g., in the automotive industry. New processes had to be developed to improve welding and paint application properties for large-scale industrial manufacture. These involved close cooperation between the producers and consumers of coated steel sheet. Within the steel industry, the continuous surface coating processes used include hot dipping, electrolytic techniques, vapor treatment, and coil coating.

The status of surface coating in relation to other production processes within the steel industry is shown in Figure 166.

The design of surface coating plants for wide steel strip essentially consists of the mechanical entry section, the process itself, and the exit section. The input and output sections are provided with pay-off reels, coiling reels, leveling machines, shears, welding machines, loopers, regulating and pulling rolls, etc.

This equipment produces a continuous strip, and enables treatment to be carried out at constant strip speed, under stable process conditions. Inspection areas for quality assurance are usually situated at the exit end.

As well as coated strip, the steel industry also produces clad steel sheet. This is a composite material that combines the properties of a carrier material which is usually cheap (e.g., carbon steel) with those of a metal more suitable for the conditions of use (e.g., corrosion-resistant steel).

5.2. Hot-Dip Coating

5.2.1. Plant and Processes

In the hot-dip coating process, the steel strip is continuously passed through molten metal. An

Figure 166. Surface coating in relation to other production processes

alloying reaction between the two metals takes place, leading to a good bond between coating and substrate.

Cold-rolled wide strip is usually used for hot-dip coating, but this is contaminated with rolling lubricant emulsion and of abraded iron fines. To ensure a good bond between the metal coating and the substrate, the surface of the strip must be thoroughly cleaned before dipping in the molten metal.

The important parts of the hot-dip coating process (Fig. 167) are [244]: the continuous furnace; the treatment zone where the metal coating is applied; cooling and final treatment.

Older plants usually have a horizontal continuous furnace which comprises a directly heated preheating furnace and indirectly heated reduction and holding zones with reducing H_2/N_2 atmospheres, followed by cooling zones. In the preheating furnace, the strip is rapidly heated to $> 550\,°C$, and is cleaned by burning off the oil

Figure 167. Hot-dip coating plant

emulsion residues. In the reduction and holding zones, the strip is heated to cause recrystallization or normalization, according to the grade of steel, to give the cold-rolled, work-hardened substrate material the desired mechanical properties.

For normal grades of thin steel strip, temperatures are 700 – 750 °C, and for IF (interstitial free) steels > 800 °C.

The strip is cooled in the cooling zones to a temperature slightly above that of the molten metal, with static cooling elements and rapid coolers.

Figure 168. Control of coating thickness
a) Coating thickness measurement; b) Jet processing nozzle (slit), c) Pass line roll; d) Stabilizing roll; e) Bottom roll

After leaving the continuous furnace, the cleaned and heated strip, under a protective gas, is fed by means of a so- called snout into the molten metal (Fig. 168), which is contained in a heated metal or ceramic vessel. Immediately after this, jet processing is carried out by blowing a gaseous medium through a slit, of the same length as the width of the strip, onto the upper and lower sides of the strip. This enables different coatings to be produced on the two sides. The coating thickness (7 – 45 µm, or 50 – 300 g/m^2) is a function of gas pressure, strip speed, nozzle – strip distance, nozzle aperture, jet angle, and the viscosity and density of the metal being removed.

The thickness of the metal coating is continuously monitored, and controlled by adjustments to the jet processing equipment.

After jet processing, the liquid metal coating passes through air cooling equipment, so that it solidifies before it comes into contact with the first roller that deflects it from the vertical.

The strip then passes through more processing equipment. It is rolled in the finishing stand to improve its technical properties or to give a uniform surface appearance. The flatness of the strip is then improved by stretch – leveling equipment.

Further chemical treatment – chromate passivation and/or oil treatment, for temporary protection of the surface against "white rust" is sometimes carried out.

In new plants (Fig. 169), the continuous furnace is usually vertical, which reduces the number of contacts between the easily damaged strip and the carrier rollers. These Plants also have alkaline cleaning equipment, with brushing and rinsing zones to remove both the emulsion residues and most of the particles of abraded

iron. The preheater in these plants is usually indirectly heated, as the emulsion residues are removed in the alkaline cleaning.

5.2.2. Other Coating Processes

Up to the late 1960s, only zinc and aluminum were used to coat steel. Corrosion resistance and working properties were later improved by using coatings based on a composite zinc – aluminum system. Table 19 lists the most important coatings, with compositions, coating thicknesses, and bath temperatures.

Zinc in the presence of moisture provides cathodic protection of the steel substrate. This is effective, even in the region of the uncoated edges, up to a steel thickness ca. 1 mm.

Aluminum has a dense outer oxide layer which reduces loss rates in various atmospheres, and gives better corrosion protection, especially at higher temperatures. The zinc – aluminum combination is selected to give the best coating properties for each application.

In the hot-dip zinc coating process, when the oxide-free steel surface is dipped, a multilayer Fe – Zn diffusion zone is formed which is then covered with a layer of zinc on removing the sheet from the bath. In batch galvanizing, uncontrolled growth of the Fe – Zn layer leads to a thick and very brittle coating with several component layers (Fig. 170) that does not readily undergo forming processes. On the other hand, a continuous zinc coating process involves short contact times between the strip and the molten

Figure 171. Control of crystal size in hot-dip zinc coatings by adding foreign nuclei
A) Zinc dust spray; B) Water – air spray

Table 19. Composition and temperature of hot-dip coating baths and coating thicknesses produced

Coating	Zn, %	Al, %	Si, %	Bath temperature, °C	Coating thickness, µm
Zinc coating	99.5				7 – 45
Monogal	99.5	0.12 – 0.30		450 – 480	7 – 15
Galvannealed	99.5				7 – 15
Galfan	95	5		420 – 450	7 – 25
Galvalume	43.4	55	1.6	600 – 620	13 – 28
Aluminum coating (type 1)		90	10	660 – 680	17 – 45

zinc. Aluminum is added to reduce the speed of the Fe – Zn reaction, leading to a relatively thin alloy layer. Compared with batch processes, this composite system permits an extreme degree of deformation without detachment of the coating.

Figure 172. Zinc spangle diameter as a function of lead content of the coating bath

When the zinc coating solidifies, the well-known zinc spangle appears, caused by lead in the zinc bath (usually 0.10 – 0.15 %). Hot zinc-coated thin strip with good forming and paint application properties must have zinc crystals that are as small and uniform as possible over the length and width of the strip. Crystal size can be controlled by nucleation or by the composition of the bath.

Figure 173. Coating steel strip on one side only (Nippon Steel)
a) Furnace; b) N_2 atmosphere; c) Coating roller; d) Zinc bath; e) Stripping nozzle

Control of the number of nuclei by the introduction of foreign nuclei has been used for some years (Fig. 171). Nuclei in the form of water, water vapor, water-soluble salts, or zinc dust are blown onto the liquid coating surface. The success of the operation depends on uniformity over the whole width of the strip.

The third method of reducing zinc spangle is to reduce the lead content (Fig. 172). As the solubility of lead in the zinc crystals is low, separate crystals tend to appear. If the lead content is $< 0.05\,\%$, the crystals are hardly visible macroscopically.

Figure 174. Hot-dip zinc coating by the Monogal process
a) Reverse-direction metal brush with zinc dust extraction; b) Nozzles; c) Zinc bath; d) Pass line roller

Steel strip coated with zinc on one side only, the other side having similar properties to those of cold-rolled strip, is required in small amounts by the automotive industry.

In the process shown in Figure 173, liquid zinc is transferred to the strip under a nitrogen atmosphere by means of a carrier roll. In the Monogal process, the zinc coating is removed from one side of the strip by brushing in the opposite direction with a metal brush (Fig. 174), and is removed by a fume extraction system. A residual layer remains on the brushed side, consisting of ca. $10\,g/m^2$ material in the form of an Fe – Zn layer. The result resembles material that has been coated by applying a hot melt to one side only.

In the Galvannealed process (Fig. 175), online treatment of the strip is carried out immediately after zinc coating. After solidification, the coating ($30 - 90\,g/m^2$, $5 - 12\,\mu m$) is heated briefly at $460 - 600\,°C$, inductively or with gas. This converts the zinc coating to a penetrating Fe – Zn alloy layer, which should have Fe content $9 - 11\,\%$ for maximum forming properties. Compared with a pure zinc coating, Fe – Zn alloy coating gives improved welding and paint adhesion properties. If the Galvannealed strip is not painted, its corrosion resistance is less good.

Figure 175. Hot-dip zinc coating by the Galvannealed process
a) Cooling zone; b) Holding zone; c) Heating zone; d) Nozzles; e) Zinc bath

A coating with the trade name Galfan was developed by the Centre de Recherches Métallurgiques in 1980. The zinc is alloyed with ca. $5\,\%$ aluminum to give a eutectic composition with melting point ca. $380\,°C$. Wettability of the steel strip is improved by including small

Figure 176. Electrolytic coating with zinc

amounts of cerium and lanthanum in the melt bath. The Galfan coating has a lower loss rate and improved forming porperties (for comparable coating thicknesses) when used without a paint coating in an industrial atmosphere.

An Al – Zn alloy (ca. 55 % Al, ca. 43 % Zn, and 1.6 % Si) was introduced by Bethlehem Steel in 1963 under the trade name Galvalume. It has a low loss rate, especially in maritime climates.

5.3. Electrolytic Coating (Electroplating)

5.3.1. Plant and Processes

In electrolytic coating (electroplating), the steel strip, which has been annealed and rolled (skin-pass rolling), is continuously passed through an aqueous electrolyte containing zinc ions (Fig. 176) [245]. An electric current causes the zinc ions to be deposited on the steel strip, which forms the cathode. The process takes place at 55 – 75 °C, so that there is no alloying with the steel strip, and the mechanical properties of the substrate are not affected. The desired coating thickness is achieved by controlling current and strip speed.

In a electroplating plant (Fig. 177), the equipment at the feed end is similar to that used for hot-dip coating, and only those features that differ from hot dipping are described here.

The surface of the cold-rolled strip must be clean so that an adherent, optically defect-free metallic coating is produced. Electrolytic coating plants have facilities for cleaning the strip, normally a combination of spray, brush, and electrolytic cleaning with alkaline cleaning solutions at 80 °C.

In cleaning facilities that use chemical solutions, multistage rinsing with brushing equipment is always provided, so that residues from the treatment solutions are removed as completely as possible.

After cleaning, many plants include stretch – leveling equipment to ensure that the strip is flat. This is necessary so that the distance between the anode and the strip can be kept small, while avoiding contact between the two (short circuits), thus minimizing electricity costs.

In the electrolytic pickling process, the strip is activated before the zinc coating stage. After cleaning and pickling, the strip enters the coating facility, in which the number of electrolytic cells is sufficient to enable the production rate to match that of the rest of the plant.

The strip can be treated to give additional temporary corrosion protection, most commonly by phosphating and/or chromate passivation.

A strip drier is always provided at the exit end of the treatment zones of an electrolytic coating plant. In the discontinuous part of the exit area, there are usually trimming shears to ensure the correct strip width.

5.3.2. Electroplating Cells

In steel strip electroplating plants, coating takes place in the electroplating cells. The strip is connected to the negative pole of a rectifier, and forms the cathode. The conduction rollers have

Figure 177. Electrolytic coating plant
a) Pay-off reels; b) Welding machine; c) Alkaline cleaning; d) Entry looper; e) Stretch-leveler; f) Pickling; g) Electroplating; h) Aftertreatment; i) Exit looper; j) Trimming shears; k) Oil treatment; l) Take-up reel

a highly wear-resistant cladding of special steel, and have to be cooled, owing to the high current which they carry. Compression rollers ensure good electrical contact. The anodes are situated on both sides of the strip, as near the strip as possible.

There are two types of anode:

1) Solid anodes of the metal being coated dissolve at a rate proportional to the current and must be replaced at regular intervals.
2) With insoluble anodes made of lead alloys, or titanium plates coated with noble metals. Zinc solutions must be added to the electrolyte.

To produce zinc or alloy coatings, sulfuric or hydrochloric acid electrolytes and soluble anodes are most often used. Addition of conducting salts, e.g., Na_2SO_4 or $(NH_4)_2SO_4$, ensures high conductivity, with current densities $> 100\,A/dm^2$.

Three types of cell can be used for electroplating (Fig. 178); horizontal and vertical cells are used for coating one or both sides, while radial cells coat one side only.

5.3.3. Coating Types

Zinc Electroplated Thin Steel Strip. Corrosion protection increases with increasing coating thickness, but workability and weldability deteriorate. A coating thickness of ca. 7.5 µm represents a good compromise.

Zinc – Nickel Coatings with 11 ± 1 % Nickel. This material has good corrosion properties, but mechanical properties are sometimes inferior to those of pure zinc coatings. Sealed Zn – Ni coatings (Durasteel) give improved workability.

Zinc – Iron Coatings. These give cathodic protection up to an iron content of 85 % in the coating. Anticorrosion and workability properties are good with iron content 15 – 25 %, while good paint application properties are obtained with iron content > 50 %. This has led to the development of a two-layer coating, the first with 10 – 25 % Fe, (the rest being Zn), the outer coating containing > 60 % Fe.

As well as these established types of coating, Zn – Co and Zn – Mn alloys are being investigated. Cobalt also shows interesting properties, even at low concentration, and can be plated at high current densities. Manganese is of great interest owing to the formation of a protective surface layer of Mn_2O_3.

Tin and Lead – Tin Coatings. Lead – tin coatings containing 10 % Sn (Terne) are mainly used to plate steel sheet for gasoline tanks. It has indifferent electrochemical behavior towards chemicals, but displays good corrosion behavior as well as good paint application properties for selected paint systems.

Tinplate is steel strip, 0.1 – 0.5 mm thick, with a tin coating of ca. 2.4 g/m^2. A solution of tin fluoroborate can be used as electrolyte. The thin strip, which forms the cathode, is passed between two rows of thin anodes. After coating, the strip is heated above 232 °C (*mp* tin), and quenched in water to give the brilliant luster of electrolytically produced tinplate. Strip speeds > 650 m/min can be reached. Tinplate is used in packaging (painted, foil- covered, or printed).

Electrolytic chromium- coated steel (ECCS) is a special type of chromium-plated thin steel strip, and is produced in a similar process. In many applications, ECCS has replaced tinplate.

5.4. Vacuum Vapor Deposition

5.4.1. Plant and Processes

In the vacuum vapor deposition process, the coating metal is deposited onto the "cold" steel strip from the vapor phase [246]. Vacuum vapor deposition is not yet established on a large scale in the steel industry, and is operated at only one location so far, where a hot-dip plant has been converted to a vapor deposition plant (Figs. 179, 180).

Vaporization is simply carried out in the zinc melting vessel. The plant has only a directly heated preheater, without alkaline cleaning. This degree of cleanliness of the strip is often adequate for the vapor process. Coating takes place in two chambers, both operating at 2.66 Pa; the vaporization capacity of the first is 350 kg/h, and that of the second chamber is 500 kg/h. Molten zinc at 460 °C is pumped into the vaporization chamber where it immediately vaporizes at the low pressure. The strip must be cooled to ca. 250 °C in the vacuum chamber so that the zinc precipitates onto the cold strip. The operating pressure is reached by successive reduction of the atmospheric pressure by squeeze rollers.

While the hot-dip process is mainly suitable for producing zinc coatings with thickness $> 60\,g/m^2$, zinc vaporization produces coatings with thickness ca. $30\,g/m^2$, often more cheaply than the electrolytic process.

5.4.2. Further Developments [247], [248]

Vacuum vapor technology is mainly suitable for coating with pure metals, alloys, chemical compounds, and composite layers that cannot be produced by hot-dip or electrolytic coating. Potential coating materials under investigation are listed below:

Metals
- Zinc
- Aluminum
- Chromium
- Titanium
- Nickel
- Copper
- Silicon

Alloys
- Nickel – chromium
- Zinc alloys, e.g., Zn – Mg, Zn – Cr, Zn – Al, Zn – Ni, Zn – Ti

Chemical compounds
- TiN, TiC
- Al_2O_3
- SiO_x

Composites
- Al – Ti, Al – Cr
- TiN – Cr
- Zn – Al
- Zn – Zn alloys

With a sufficient number of vaporizing chambers vapor coating could be carried out at rates of 350 – 400 m/min. A vaporizing plant could be incorporated into an existing continuous annealing furnace, adding to the production capacity for coated steel strip. As only one side is coated in each chamber, it would be possible to coat either one side or both.

5.5. Coil Coating

5.5.1. Plant and Processes

In the production of coil- coated thin sheet [249], the substrate material can be cold-rolled strip, zinc- coated thin sheet (hot-dip or electroplated), aluminum strip, or special steel strip. Liquid paint or foil is applied to these carrier materials by rolling.

A coil coating plant (Fig. 181) consists of the feeding equipment, strip cleaning, chemical pretreatment, coating areas for primer and topcoat with the associated drying ovens, and the exit equipment. The strip is cleaned by methods similar to those used in zinc electroplating, but in this case the surface is then phosphated or chromated. For this, the solutions are sprayed at ca. 40 °C, under pressure. The strip is then cooled with deionized water and passivated. The chromate or phosphate coating provides corrosion protection for the whole system, and improves adhesion of the polymer coating. Before the strip

is introduced into the coating station, this precoat is dried with hot air.

Figure 182. Typical coil coating systems
A) Two rollers, reverse rotation; B) Three rollers, complete reverse rotation

Primer or undercoat is applied at the first coating station (Fig. 182). The paint is usually applied by typical rolling machines, running in the opposite direction to the strip, one on each side of the strip, each paint roller having two or three feed rollers, depending on the coating material. As a rule, a chromium-plated dipping roller supplies the paint from a tank to a rubber-coated roller running in the opposite direction to the strip, and applies a paint film at a rate controlled by a special roller. The primer can be applied to the upper and lower side of the strip. The strip then usually passes into the first drying oven in which it hangs freely, and is heated to ca. 200 – 240 °C, depending on the coating system. The strip with its coat of primer is then cooled by air and water, and passes to the second coating station. The topcoat is applied on one or both sides, usually only the upper side. The coating is then backed in the second drying oven at ca. 240 – 260 °C. Before the strip passes to the air or water cooling area, it can be provided with a decorative and/or protective film. These laminates are applied under very precise conditions of temperature and pressure. If a decorative foil is used, an adhesive is applied instead of the top coat in the second coating station.

Coating thicknesses, which depend on the coating system, are continuously monitored over short distances by integrating thickness measuring equipment, and are maintained within very close tolerances by varying the rotation speed or the application pressure of the coating rollers.

5.5.2. Coating Systems (Fig. 183, Table 20)

The liquid coatings used are paints, based on polyester and acrylic resins, poly(vinyl chloride) plastisols, and poly(vinylidene fluoride). More recently, polyurethane paint systems have been used in special applications. Zincrometal and Inmozinc consist of thin steel sheet coated with zinc dust colors. Printed or single color poly(vinyl chloride) films are applied by rolling with an adhesive activated by hot air, and the same process is used for poly(vinyl fluoride) films. The coated or laminated material can be provided with additional protection against handling and assembly operations by means of adhesive polyethylene protective films, applied hot or cold. Coating thicknesses are usually 15 – 300 µm.

Table 20. Coating materials and thickness ranges of coating films

Coating materials	Abbreviation	Usual range of film thickness, µm

5.6. Roll-Bonded Cladding [250], [251]

5.6.1. Principles

In roll-bonding (cladding), two or more materials, which are usually flat, are pressure welded together. The process can be carried out with cold or preheated materials (cold roll-bonding or hot roll-bonding).

In continuous cold pressure welding of strip material, two metallic solids are bonded strongly together by high pressure, which causes plastic deformation. The adhesive bond can only be assured if the surfaces are clean and have a well defined surface structure (roughness).

The surfaces must be brought together under pressure until their distance apart is of the order of interatomic distances. As surfaces of technical quality are always covered with a very thin oxide layer, these layers must be broken by deformation. In roll-bonding, it is therefore necessary to stretch the surface, with exclusion of gas, so that new reactive surfaces are exposed by plastic flow. These are then brought into contact at interatomic distances, so that a strong bond can be formed by adhesion. The bond strength is increased by subsequent annealing homogenization.

Table 21. Substrate cladding materials for cold rollbonding

Substrate materials	Cladding materials
Iron	Corrosion-resistant steels
Steel	High-temperature steels
	Ni and Ni alloys
	Cu and Cu alloys
	Aluminum
	Noble metals
	Special metals (Ti, Ta, Mo)

5.6.2. The Process (Fig. 184)

In the production of roll-bonded steels, surface pretreatment is very important. The necessary conditions are:

1) Complete absence of grease
2) A clean, freshly activated metal surface
3) A roughened surface, produced by stretching

After pretreatment, the freshly brushed steel is fed, with the cladding material, into the roll nip, and deformed in one roll pass, the extent of deformation being 50 – 70 %.

5.6.3. Variations

In roll-bonding, a composite material is produced which often combines the special prop-

Figure 184. Production of roll-bonded steel strip

erties of the individual components in an ideal manner. For cost effectiveness, a cheap substrate material is often plated with an expensive, corrosion-resistant, acid-resistant, or heat-resistant material (Table 21).

Figure 185. Phase diagram of Fe – Cr [254]

5.7. Summary

Surface-coated thin steel strip was developed to improve, e.g., the corrosion properties of the steel, or to provide a decorative appearance. The user must consider a range of properties, such as workability, welding properties, adhesive properties, and paint application properties. Each type of surface treatment has strengths and weaknesses compared with competitive processes.

Other surface treatment methods are likely to become available, including electro- and plasma polymerization, electrolytic deposition of Al and Ti from organic solutions, plasma spraying, ion implantation, and cathodic sputtering.

Figure 186. Phase diagram of Fe – Mn [255]

6. Uses

6.1. Fundamentals

6.1.1. Microstructure

6.1.1.1. Introduction

At room temperature, pure iron has a body-centered cubic structure. The solubility of carbon is < 0.001 wt % in this phase, which is known as α-iron. On heating, α-iron is transformed at 911 °C into the face-centered cubic γ-phase. This γ-iron can dissolve ca. 2 wt % carbon as a solid solution. On cooling this, transformation of γ-iron to α-iron occurs and carbon is precipitated as carbide Fe_3C. In the heat treatment of transformable steels, they are heated until the γ-phase is formed, so when this is cooled more or less quickly, metastable states may be produced, and the precipitation of Fe_3C, which in equilibrium is associated with the formation of α-phase, is more or less suppressed. The range of applications of steel depends on the fact that heat treatment can induce all the transitions between the metastable states, and those states effectively correspond to equilibrium conditions, so that a large number of microstructures and combinations of properties can be produced [252], [253]. Another method of modifying steel consists of adding alloying elements to stabilize the α-phase up to the melting point, or conversely to cause the γ-phase to be stable down to room temperature. These possibilities are mainly used to improve corrosion resistance or to achieve particular physical properties.

In the following discussion, important phase diagrams of the iron alloys are considered, and the microstructures and conditions needed to produce them are described. The description of the properties (Section 6.1.2) then provides an understanding of the heat treatment of steels (Section 6.1.3). In Section 6.2, the important steel groups and their properties are reviewed.

Figure 187. Phase diagram of the metastable state Fe – Fe_3C [257]

6.1.1.2. Phase Diagrams of Iron Alloys

The phase diagram of iron – chromium for low chromium content is shown in Figure 185 [254]. With chromium content > 15 wt %, γ-iron is no longer formed, and the α-iron is stable from room temperature to the melting point [255]. Figure 186 shows that with ca. 45 wt % manganese, the γ-iron is stable almost to room temperature. In commercial steels, the addition of carbon increases this stability range further. Like chromium, the alloying elements silicon and molybdenum limit the range of existence of γ-iron, and, like manganese, nickel and carbon, extend this range. However, the effect of the alloying elements is not additive. In a steel containing 18 % chromium and 10 % nickel, γ-iron is stable from room temperature to the melting point. These phase diagrams can be calculated from thermodynamic data [256], a compilation of the most important two- and three- component systems having been prepared [254], [257–262].

Figure 188. Quasibinary section through the three-component system Fe – M – M_3C [299]

In plain carbon steels, the metastable Fe_3C phase is of great importance (Fig. 187) [257]. This phase is stable for long periods under technical conditions of heating and cooling, especially if a solid solution $(Fe, Mn)_3C$ is formed in the presence of the usual manganese content. In Fe – Cr –C systems, $(Fe, Cr)_3C$ is stable if more than ca. 0.7 wt % chromium is present [254]. Figure 188 shows a quasibinary section through an Fe – M – M_3C system, where M represents a metal. For technical applications, the temperature limits of the phase fields during heating at 3 °C/min are measured, and are termed the Ac temperatures. The relationship of the Ac temperatures to the boundaries of the phase fields can be seen from Figure 188. Alloy steels, which are multicomponent systems containing Fe and C, can contain not only M_3C, but also the carbides M_7C_3, $M_{23}C_6$, M_2C, MC, and intermetallic phases. In these cases, the simple scheme shown in Figure 188 is not valid.

Figure 189. Parameters for the quantitative characterization of the constituents of a microstructure

6.1.1.3. Definitions

Steels are polycrystalline materials. A crystallite is a region of a phase with uniform crystal orientation. The phases which the phase diagram shows to be present or metastable states form crystallites, separated from each other by grain boundaries or phase boundaries [263]. In addition, the microstructure includes lattice defects, such as vacancies and dislocations [264], [265]. For a quantitative description of microstructure, the parameters in Figure 189 must be given for each crystallite and each defect [266–268]. A typical example of a phase is α-iron. More than one phase can exist within a crystallite region if ordered arrangements or coherent precipitates are present. The chemical composition inside a crystallite must also be given, sometimes as a function of location. The orientation must be

given for both the lattice and the spatial position of nonspherical particles. The texture within a specimen is determined by the orientation of individual crystallites [269], [270]. An example of a defect is a step dislocation [271].

Figure 190. Time – temperature austenitization (TTA) diagram for the isothermal austenitization of Ck 45 steel, including lines of equal grain size of the austenite [299]

The geometric parameters (Fig. 189) describe a spatial arrangement of phases and defects. However, two-dimensional polished sections enable only the volume fraction and the specific surface to be determined. Three-dimensional parameters, such as particle density, require that the samples be examined in serial sections, which is very difficult [272]; in many cases, approximations are based on polished section measurements [266].

In steel microstructures, γ-iron is referred to as austenite, and α-iron as ferrite. The term cementite is used for the carbide M_3C. Sulfides, oxides, and carbonitrides, e.g., Nb(C, N), are often referred to as nonmetallic inclusions. Single-phase microstructures occur only in steels with ferrite or austenite as the stable phase. In plain carbon steels, on cooling from the austenite temperature range (Fig. 187), ferrite and carbide are formed, but, under production conditions, these are not in equilibrium. The size of such carbides ranges from a few nanometers to a few micrometers [273].

The iron – cementite phase diagram (Fig. 187) can be used as a first approximation to determine the phases present at equilibrium in plain carbon steels. In the range of carbon content below the eutectoid point S, an austenite, e.g., containing 0.3 wt % C, transforms partially to the so- called proeutectoid ferrite during cooling from 1000 °C. At temperatures below the line P – S – K, ferrite and carbide form simultaneously from the residual austenite in the eutectoid reaction. Steels of this type are known

Figure 191. A) Time – temperature transformation (TTT) diagram for the isothermal transformation of Ck 45 steel [299] Austenitization: 850 °C for 15 min
B) Volume fraction of various microstructures at various temperatures and hardness after cooling to room temperatureA = austenite; F = ferrite; P = pearlite; B = bainite; M = martensite

Figure 192. A) Time – temperature transformation (TTT) diagram for continuous cooling of Ck 45 steel
B) Volume fractions of the various structures [299]

as hypoeutectoid. With carbon content above the eutectoid point S (hypereutectoid steels), transformation of the austenite begins during cooling with precipitation of carbide. The carbon content at the eutectoid point is considerably altered by the addition of alloying elements [253].

6.1.1.4. Microstructures in Plain Carbon Steels

Austenite Formation. Figure 190 illustrates how austenite is formed by an arrangement of α-iron and M_3C (ferrite and carbide) in the steel Ck 45 (see Section 6.2.1) by an isothermal temperature – time treatment [274–276]. The first line Ac_{1b}, which is reached at 800 °C after 0.4 s, represents the formation of 1 vol % γ-iron (austenite). The last line Ac_3, reached at 800 °C after 2000 s, represents the formation of 99 vol % γ-iron. The area $\alpha + \gamma + M_3C$ corresponds to the three-phase equilibrium in Figure 188. Above 775 °C, the single-phase area of γ-iron (austenite) is reached only after long heating times. In practice, austenitization is carried out at temperatures 30 – 50 °C above the tem-

perature Ac_3 measured on slow heating (830 °C in the previous case). In the austenite formed, which is at first inhomogeneous, the carbon is enriched in regions where carbides have gone into solution. With increasing temperature and holding time, the austenite becomes homogeneous. With increasing austenitization temperature and time, the grain size of the austenite also increases (Fig. 190). If the austenite grain size is small, an improvement in toughness is obtained for a given yield strength (see Section 6.1.2). In practice, austenitizing is a compromise between homogeneous austenite, which requires high temperatures and long heating times, and fine austenite grain, which requires low austenitizing temperatures and short heating times.

Austenite Transformation. On cooling austenite, microstructures known as ferrite, pearlite, bainite, and martensite are formed as metastable states [276]. The formation of ferrite, pearlite, and bainite is mainly diffusion controlled. Figure 191 shows the effect of the change of the time interval between the beginning and end of the transformation in the pearlite range and the bainite range as a function of temperature. The transformations overlap [277], [278]. At 550 °C, the transformation begins after 1 s, with formation of ferrite. It ends with the transformation to pearlite, and is complete after 6 s. At 480 °C, the transformation of austenite to bainite is superseded by a transformation to pearlite. The maximum in the transformation rate to pearlite at 550 °C occurs because the nucleation rate passes through a maximum as the temperature decreases, while the growth rate (a diffusion process) continuously decreases with decreasing temperature. The martensite transformation is not diffusion controlled, so, starting at temperatures below M_s (the martensite start temperature), it proceeds at approximately sonic speed, independently of time [279].

Industrial heat treatment processes to produce a microstructure usually involve continuous cooling, for cost reasons. Figure 192 shows the time – temperature diagram for continuous cooling of Ck 45 steel. As the cooling curves are all similar, they may be characterized by quoting the duration of the cooling between 800 and 500 °C ($t_{8/5}$) or the cooling time to 500 °C. From each cooling curve, the temperatures and times can be read off for the start of formation of ferrite, pearlite, bainite, or martensite and also for the end of the transformation process [278], [280].

Ferrite. Figure 192 shows that Ck 45 steel with $t_{8/5} = 2 - 10^4$ s first forms ferrite, with carbon content fairly close to that predicted from the phase diagram. This ferrite forms either as a film on the austenite grain boundaries (Fig. 193) or as separate grains (Fig. 194) [281–283]. Its properties mainly correspond to those of pure iron.

Figure 193. Ferrite (white) on the former austenite grain boundaries and pearlite (gray or black)
Ck 45 steel, 900 °C for 15 min, 530 °C in 300 s, water quench; etched with nital

Figure 194. Globular ferrite (white) and pearlite (gray or black)
Ck 15 steel, 900 °C for 15 min, $t_{8/5} = 100$ s; etched with nital

Pearlite. After the ferrite, Ck 45 steel forms pearlite (Fig. 192), a lamellar arrangement of ferrite and cementite, formed simultaneously from the austenite (Fig. 195) [281]. This dou-

ble precipitation is much more rapid than the independent transformation of the austenite into ferrite with precipitation of cementite that would be expected from the equilibrium. The transformation to pearlite is diffusion controlled. The formation of ferrite, which has a low carbon content, causes carbon enrichment in the surrounding austenite until the formation of cementite (ca. 6.7 wt % carbon) is possible. The volume ratio of ferrite to cementite in the pearlite can fluctuate over a wide range, as can be seen from the volume fractions (Fig. 191 B). Thus, by suitable heat treatment, a microstructure of pure pearlite can be produced in steels containing 0.3 wt % carbon, just as in steels containing 1.2 wt %.

Figure 195. Pearlite, lamellar arrangement of cementite (gray or black) and ferrite (white)
C 70 steel, 800 °C for 15 min, $t_{8/5}$ = 10 000 s; etched with sodium picrate

Martensite. Martensite is formed without diffusion by an ordered movement of atoms over short distances [279]. This movement is defined by the crystal microstructures of γ-iron and α-iron. The carbon dissolved in the austenite as a solid solution remains in solution during martensite formation, which leads to very marked lattice distortion. Platelets are formed, which appear needle-like in the polished section (Fig. 196) [281]. The transformation of austenite to martensite is associated with a volume increase of 0.5 – 1 %, depending on the alloy content. Figure 192 shows that if Ck 45 steel is to form martensite only, $t_{8/5}$ must be < 1.2 s. Of all steel microstructures, martensite has the highest hardness and yield strength, although martensite with carbon content > 0.2 wt % is very brittle. For lower carbon content, so- called lath marten-site, is formed. This has very good toughness properties [284], although the hardness of martensite decreases with decreasing carbon content (Fig. 197). At a given temperature, martensite formation is incomplete. Depending on the chemical composition, steel must be cooled ca. 250 °C below M_s to transform 99 % of the austenite into martensite.

Figure 196. Martensite in Ck 45 steel
850 °C for 15 min, water quench; etched with nital

Figure 197. Hardness of martensite in plain carbon steels as a function of the content of dissolved carbon in the austenite [299]

Bainite. Bainite is formed at a temperature between that of the transformation of austenite to ferrite and pearlite and that of its transformation into martensite. The transformation is partly diffusion controlled, and partly proceeds by a lattice-shearing mechanism similar to that for martensite. By a combination of these mechanisms, the transformation of austenite to bainite can be much more rapid than the transformation to pearlite at a given temperature (see Fig. 191) [285], [286].

Bainite is an arrangement of ferrite and carbides detectable, by optical microscopy, only at high formation temperatures (Fig. 198) [281]. After formation just above M_s, the bainite is very fine (Fig. 199), and cannot be distinguished from tempered microstructures (see below). Bainite formation at a given temperature is time dependent (see Fig. 191). However, at lower M_s, the diffusion processes leading to bainite formation are slower, so that bainite formation does not proceed to completion in technically realistic times. In some steels, there are regions in which bainite formation is incomplete, even at ca. 450 °C [287].

Figure 198. Coarse bainite in a steel with 0.2 % C and 2 % Mo
950 °C for 15 min, cooling to 500 °C in 100 s; etched with nital

Figure 199. Fine bainite in 34 Cr 4 steel
850 °C for 15 min, cooling to 375 °C in 500 s, water quench; etched with nital

In a continuous cooling process, the various microstructures appear in sequence (Fig. 192). When Ck 45 steel is cooled to 500 °C in 8 s, ferrite is formed at 650 – 610 °C, followed by pearlite down to 575 °C, then bainite, and then martensite below 290 °C (Fig. 192). Depending on the way these microstructures grow and the temperature range involved, the various components of the microstructure are separable only rarely and with difficulty. It should be mentioned that the interparticle distances for pearlitic carbide are usually very much smaller than those for bainite formed at the same temperature (Fig. 200).

Figure 200. Pearlite and bainite in 41 Cr 4 steel [299]
840 °C for 5 min, cooling to 510 °C in 4000 s, water quench; etched with nital

Microstructures after Tempering. The carbon held in solution within the lattice on martensite formation can form carbide precipitates by diffusion if the temperature is increased [253], [276]. Precipitation takes place more rapidly and to a greater extent as the annealing temperature is increased. Precipitation of carbide reduces the lattice distortion, so that the hardness and yield strength steadily decrease and the toughness increases. Thus, choice of annealing temperature enables any desired intermediate stage to be produced with yield strength between that of a martensite and that of a soft-annealed microstructure (see Section 6.1.3.2). Annealing also gives a very uniform carbide distribution, which greatly improves the toughness of the material for a given yield strength [288] (see Section 6.1.3.2).

6.1.1.5. Microstructures of Alloy Steels

The mechanisms of microstructure formation described above also apply to alloy steels where

the volume ratios of individual phases change, particularly if carbide and nitride phases are formed, which does not occur with plain carbon steels. In tool steels, a quenched and tempered microstructure is produced with included coarse carbides which have an abrasion-resistant effect (Fig. 201). The matrix strength can be controlled by choice of annealing temperature [289]. In alloy tool steels, the hardness of chromium and tungsten carbides is also utilized. Furthermore, precipitation of carbides as very fine particles on annealing these alloys sometimes starts only at ca. 500 °C, so that, unlike the plain carbon steels, these materials can be used at high temperature [290]. The growth of alloy-rich carbides, e.g., M_7C_3 or MC, is determined by diffusion of the alloying elements, which is much slower than that of the carbon. The carbide particles remain small for a long time after they are formed, so that the yield strength remains high, decreasing only as the particle size increases. This effect, known as precipitation hardening (see Section 6.1.3.3), leads to an increase in the high-temperature creep resistance of high-temperature steels, as the precipitates are very small [289], [291].

Figure 201. Quenched and tempered microstructure of C 130 tool steel
Coarse, undissolved carbides (white) in a matrix of very finely divided carbides in ferrite, 810 °C for 15 min, water quench, 150 °C for 10 min, aircooling; etched with nital

In maraging steels, precipitation of intermetallic phases leads to precipitation hardening, and increases the yield stength of a low carbon martensite to ca. 2000 MPa [292]. In nontransformable austenitic and ferritic steels, hardening by martensite formation is not possible. Thus, precipitation hardening is an important method of increasing strength, in addition to grain refinement and work hardening [293] (see Section 6.1.2).

Corrosion-resistant steels usually have a pure ferritic or austenitic microstructure [294–296]. However, duplex steels have a microstructure consisting of approximately 50 % austenite and 50 % ferrite [297]. In corrosion-resistant steels, the chemical composition of the phases and the type and arrangement of the carbides have an extremely important influence on their resistance to aggressive media [298].

6.1.2. Properties

6.1.2.1. Mechanical Properties

Steel must have high strength and good toughness properties. Following the plan of the comprehensive treatment of mechanical properties in *Werkstoffkunde Stahl* [300], [301], the first part of this section describes conditions under which high strengths can be achieved by modification of the microstructure. The discussion then moves to toughness requirements, definitions of this property for particular applications, and ways of influencing it through the microstructure. The discussion deals first with axial stress conditions at and below room temperature. If the direction of the stress is changed, special effects occur, which are described later. As steel is also used at higher temperatures, methods of controlling strength properties under these conditions are described in the last section.

6.1.2.1.1. Behavior Under Unidirectional Loads, at and Below Room Temperature [302–309]

The Stress – Strain Curve [310], [311]. At first, iron deforms elastically under an applied force. The relationship between the stress and the resulting strain (or elongation) is expressed by Hooke's law:

$$\sigma = F/S = E\varepsilon = E\,(l - l_o)\,/l_o$$

where F is the force, S the cross section, l_o the initial length, and l the length of the test piece subjected to a tensile stress. The modulus of elasticity E is 216 000 MPa, but this value depends

Figure 202. Movement of an edge dislocation (represented by the symbol ⊥) across a cubic lattice [314]
A) Initial state; B) Burgers circuit around a dislocation; C) Burgers circuit in an undisturbed lattice after slipping

on the orientation. A similar relationship exists between shear stress and shear strain; the proportionality factor G is the modulus of rigidity or shear modulus. The relationship between the Young's modulus E and the shear modulus is:

$$G = E / [2(1+\nu)]$$

in which Poisson's ratio ν for iron is 0.3.

In the elastic range the strain is reversible, but beyond a specific stress limit, permanent plastic deformation begins. Experiment shows that this phenomenon is associated with slip of crystal planes along the direction of greatest shear stress. The lattice structure is preserved. According to theory, this slip should require stresses a thousand times as great as the measured values in pure iron. The discrepancy is explained by the presence of linear lattice defects, i.e., dislocations [312–314]. In a linear edge dislocation (Fig. 202), slip takes place perpendicular to the dislocation line. In a screw dislocation (Fig. 203), slip is parallel to the dislocation line. With the aid of these and other types of dislocation, in which slip takes place at an angle 0 – 90° to the dislocation line, the plastic deformation of iron can be well understood. As a dislocation causes a slip of one interatomic distance, and can only move over a short distance in the lattice before the movement stops at an obstacle (Fig. 204 A), many dislocations are necessary for deformation. The number of dislocations must increase continuously during the deformation process. A mechanism for the production of dislocations is illustrated in Figure 204 C (the Frank – Read source). This is based on the fact that dislocations of opposite sign annihilate each other. In the Orowan mechanism (Fig. 204 B), the dislocation passes the obstacles, leaving dislocation loops around them. This illustrates a possible mechanism to hinder

the movement of a dislocation, which leads to an increase in strength as the stress moves the dislocation through the lattice.

Figure 203. Burgers circuit
A) Burgers circuit around a screw dislocation; B) Burgers circuit in an undisturbed lattice

In crystals that have not been deformed, the dislocation density is $10^6 - 10^8\ \mathrm{cm}^{-2}$ and can increase to ca. $10^{12}\ \mathrm{cm}^{-2}$ on deformation. This figure can be regarded either as the number of intersections of dislocations with an area of 1 cm^2, or as the total length of the dislocation lines in a volume of 1 cm^3.

The most important method of measuring the relationship between stress and strain is the tensile test. A cyclindrical test piece is deformed by an axial tensile load at a constant rate of elongation or constant rate of increase of tensile stress (DIN 50 145, 50 146). Figure 205 shows the technical or conventional stress – strain curve (curve a). Dividing the force F by the initial cross section S_o, gives the stress $\sigma = F/S_o$, and the strain is calculated from the elongation. Initially, Hooke's law is obeyed. As plastic deformation begins, the stresses can be determined at which permanent deformations take place, e.g., the technical yield stress with a permanent deformation of 0.01 % (0.01 % offset), the 0.2 % offset yield stress $R_{p0.2}$, or the 1 % offset yield stress R_{p1}. Steel often shows a well-defined upper yield point R_{eH} and a lower yield point R_{eL}. These will be discussed later.

The transition from the elastic to the plastic range occurs when movement of dislocations takes place under the action of applied stress. The magnitude of the stress required is determined by the structure. The resistance to further deformation, i.e., the strain hardening, is the result of the increase in the number of dislocations, which prevents further movement of the dislocations. This hardening has the following effect: After the elastic limit has been exceeded, the regions which deform first, and hence have a higher stress owing to the reduction in cross section, do not flow further until the remainder of the test piece has reached the same cross section. However, as hardening decreases with increasing elongation, at a certain strain the increase in stress is no longer compensated for. Thus, further deformation takes place at a fortuitously deformed place, and necking occurs. The maximum in curve (a) of Figure 205 corresponds to this. The force F_m divided by the initial cross section S_o is referred to as the ultimate tensile strength R_m. Tensile test measurements also enable determination of the uniform elongation (i.e., without necking) A_{gl}; this is the elongation at maximum force. A is the elongation at rupture, and Z is defined as the reduction of area at rupture:

$$Z = (S_o - S_u)/S_o$$

where S_u is the cross section at rupture. Because of the necking, A depends on the geometry of the sample. The reduction of area is a significant parameter for characterizing toughness in tensile tests.

Figure 204. Behavior of dislocations at obstacles
A) Elongation of dislocation line l by the amount $2s$ under a stress; B) Bypassing of particles by a dislocation (Orowan mechanism); C) Production of dislocations (Frank – Read source)

To determine the predominant true stress in the test piece, the force must be divided by the smallest cross section S. The corresponding true elongation ε_w is obtained for elongations up to the maximum force at which the test piece deforms uniformly:

$$\varepsilon_w = \int_{l_0}^{l} (dl/l) = \ln(l/l_o) = \ln(l+\varepsilon)$$

Over the whole region:

$$\varepsilon_w = \ln(S_0/S)$$

This is due to the constant volume relationship

$$l_0 S_0 = l S$$

In Figure 205, the true stress, determined as described, is shown as curve (b); for exact calculations, it must be corrected to take account of the multiaxial stress condition when necking takes place (curve c) [315].

At maximum load, $dF = 0$, so the relationship between ultimate tensile strength and the start of necking can also be derived graphically. Figure 206 A shows stress – strain curves for steels of various strengths [316]. Figure 206 B shows the true stress – true strain curves, and the strain hardening as functions of the true strain. The condition $dF = 0$ means that, at the start of necking:

$$\sigma_w = d\sigma_w / d\varepsilon_w$$

For higher yield stresses, the start of necking is shifted to continually decreasing strain values.

Figure 205. Stress – strain curve at room temperature of an unalloyed, fully killed steel with ca. 0.15 % C, 0.4 % Si, and 1.4 % Mn (St 52-3).

Steels often show a discontinuous transition from the elastic to the plastic region – the distinct limit of elasticity or yield point (see Fig. 205) [317]. The Hooke's law straight line rises to the upper yield point. A reduction in stress then takes place to the value for the lower yield point, where a narrow deformed region is produced in the test piece (the Lüders band) at 45° to the direction of the tensile load. This band broadens at the stress of the lower yield point, until the whole test piece is deformed by this amount. Further deformation takes place uniformly over the whole volume. The cause of this distinct yield point, according to COTTRELL [318], is blocking of the dislocations by carbon and nitrogen atoms, caused by elastic interaction of the stress fields at a dislocation and at the interstitial foreign atoms (Cottrell atmosphere). This blockage can occur if the diffusion rate of carbon or nitrogen atoms is high enough, e.g., in aging (precipitation hardening) on cooling from the rolling temperature or after heat treatment (Fig. 207), or during the deformation process in strain aging (Fig. 208) [319], [320].

Figure 207. Stress – strain curves for an iron – carbon alloy with 0.01 % C after quenching from 720 °C and various aging times at 60 °C [319]

Figure 208. Load – elongation curve of a steel with 0.035 % C, 0.36 % Mn, and 0.003 % N at various temperatures
Strain rate $6.2 \times 10^{-5}\ s^{-1}$ [320]

Figure 209. Effect of temperature on lower yield stress R_{eL}, ultimate tensile strength R_m, and rupture stress σ_R of a steel with 0.089 % C (C 10) and average grain diameter 16.8 µm at various strain rates $\dot{\varepsilon}$ [321]

The values determined from the stress – strain curve depend on both test temperature and strain rate. In Figures 209 and 210, the changes in stress and strain values due to changes in the loading rate below room temperature are shown as an example. Lower yield stress, ultimate tensile strength, and rupture stress increase with decreasing temperature and increasing loading rate. At first, the uniform elongation (without necking) and elongation at rupture remain approximately constant, and the Lüders elongation increases. At lower temperature, the elongation values decrease, but the strength values increase, owing to a change in the rupture mechanism, as discussed below.

If the strain rate is increased further, the result shown in Figure 211 is observed. Assuming thermally activated dislocation movement, all the points lie on a common curve if the results are plotted against activation energies. There is a narrow scatter for the yield points (Fig. 212). This does not apply to ultimate tensile strengths if these are plotted in a similar way, as, under rapid, adiabatic conditions, the energy of deformation can raise the temperature, whereas isothermal conditions predominate at lower strain rates [321].

Many attempts have been made to describe the true stress – true strain curves mathematically. LUDWIK has proposed the equation:

Figure 210. Effect of temperature on Lüders strain $\varepsilon_{Lüd}$, uniform elongation A_{gl}, and elongation at rupture A of the steel referred to in Figure 209 [321]

Figure 211. Effect of temperature on lower yield stress R_{eL} at various strain rates of a high-strength, fine-grained steel with 0.16 % C, 0.63 % Ni, and 0.16 % V (FeE 460) in the normalized condition [315]

Figure 212. Lower yield stress R_{eL} and ultimate tensile strength R_m of the steel referred to in Figure 211 plotted against the activation energy ΔG for yielding at various strain rates $\dot{\varepsilon}$ [315]
σ_i = athermal fraction of yield point; $\sigma*$ = thermal fraction of yield point; $\sigma_o^* = \sigma*_{max}$

$$\sigma_w = \sigma_o + K_L \varepsilon_w^n$$

This has been simplified by HOLLOMON to:

$$\sigma_w = K'_L \varepsilon_w^{n'}$$

where σ_w is the true stress, σ_o the yield stress, K_L a constant, ε_w the true strain, and n the exponent. This formula adequately describes the properties of many steels, but n' decreases with increasing yield stress, while the strength properties do not change. The equation:

$$n' = \varepsilon_{wgl}$$

is correct, as shown by differentiation of the equation, in which ε_{wgl} represents the uniform

strain, but n' does not represent the hardening behavior.

Figure 213. Lower yield stress R_{eL} plotted against the reciprocal of the square root of the average ferrite grain diameter d (mm) of a steel with 0.089 % C (C 10) at various testing temperatures and strain rates [339]

Figure 214. Effect of testing temperature and strain rate on the friction stress σ_{iy} for the steel referred to in Figure 213 [339]

Phenomenological methods can be applied to dislocation theory to obtain various mathematical formulae for the stress – strain curves, enabling approximate correlation with the microstructure [322–324].

The flow properties of steel can be investigated by other experimental methods. By upsetting a cylinder, the yield stress is determined from the ratio of the force to the instantaneous surface area as upsetting proceeds [325], [326]. Friction at the end faces leads to barrel deformation of the test piece, which can be avoided by appropriate experimental techniques. In the torsion test [327], the moment is determined as a function of the angle of rotation. The shear strain at any point on the diameter is calculated as a function of the shear stress at the outer edge. This technique is mainly used to determine properties at high temperature. Bending tests [328], [329] are used to determine strength properties of brittle materials. Strength properties can also be estimated from hardness measurements [330].

Methods of Increasing Strength [331–335]. All processes for increasing the strength of steel depend on hindering the movement of dislocations. These can be classified in accordance with their dimensions:

1) Zero-dimensional obstacles (e.g., point defects and foreign atoms)
2) One-dimensional linear obstacles (dislocations)
3) Two-dimensional surfaces (grain boundaries)
4) Three-dimensional obstacles (precipitates)

The discussion starts with the effect of grain size, as this shows very clear correlations.

Strength increases as grain size decreases [336–339]. The yield point of unalloyed steel is inversely proportional to the square root of the ferrite grain size. This is represented by the Hall – Petch equation:

$$R_{\mathrm{eL}} = \sigma_{iy} + k_y d^{-1/2}$$

where σ_{iy} represents the frictional stress, k_y the grain boundary resistance, and d the average diameter of the ferrite grains.

Figure 213 shows the lower yield point as a function of the reciprocal of the square root of the grain diameter for temperatures between room temperature and − 196 °C for two strain

rates. The linear Hall – Petch relationship is observed. Figure 214 shows friction stress as a function of testing temperature. The values of friction stress are obtained by extrapolation of the straight lines in Figure 213 onto the y-axis. The friction stress σ_{iy} represents the resistance of very large grains to dislocation motion.

Figure 215. Effect on testing temperature and strain rate on the grain boundary resistance k_y for the steel referred to in Figure 213 [339]

Figure 216. Effect on alloy content on the lower yield stress of ferrite at room temperature [332]

Strain rate and temperature have a considerable effect on the frictional stress. The grain boundary resistance is approximately independent of strain rate and temperature (Fig. 215). The higher value at – 196 °C is due to the change in the deformation mechanism from dislocation motion to twin formation.

The Hall – Petch equation is also valid for the yield stresses in the extended stress – strain curve. The grain boundary resistance is then smaller than at the lower yield point.

Grain refining is an important method of increasing strength, as toughness is also improved.

The mechanism of strength improvement by foreign atoms [340] is mainly interaction between the stress fields at the dislocations and the foreign atoms. Interstitial atoms have a stronger effect than foreign atoms in substitution solid solutions, as they are more firmly fixed (Fig. 216). The effect of the foreign atoms is limited by their solubility. The extreme hardness of martensite is caused on quenching by "freezing" the dissolved carbon atoms in the austenite, "folding" them into the body-centered cubic lattice; this produces an extreme degree of supersaturation with a corresponding increase in hardness.

Figure 217. Yield stress of α-iron as a function of dislocation density ϱ [341]

Dislocations are also obstacles [341]. Increase in dislocation density on deformation leads to an increase in strength and hence an increase in yield stress (Fig. 217). Ductility is progressively reduced by prestraining.

Precipitates hinder the movement of dislocations very effectively [342]. Finely dispersed precipitates, which have only a slight misfit to the matrix, are sliced by dislocations. Larger precipitates are enveloped by dislocation loops (Orowan mechanism; Fig. 218). Precipitate formation with time, and the change in the yield stress are shown in Figure 219.

Figure 218. Calculated increase in the yield stress $\Delta\sigma_P$ of α-iron by hard particles in various volume fractions v_P Hatched area: region of microalloyed structural steels [343]

Figure 219. Formation and growth of nuclei on annealing a solid solution, and changes in yield stress with time [342]. Nuclei of the critical size d_c develop at time t_c

Different mechanisms of increasing strength may be combined. Figure 220 shows how grain refining and precipitation hardening overlap. The left lower region of the diagram shows how repeatedly austenitizing a steel (ca. 0.1 % C and 1 % Mn) reduces grain size and hence increases yield stress. The x-axis is the reciprocal of the square root of the grain diameter, so Hall – Petch straight lines are obtained. If 0.2 % Nb is added and the steel is normalized, grain size is considerably reduced and yield stress increases. Niobium carbonitrides act as obstacles to grain growth during normalization. If the steel is heated to 1100 – 1200 °C and cooled in air, considerably higher yield stresses are obtained, as these carbonitrides dissolve and are reprecipitated on air cooling. However, grain size increases, which adversely affects the toughness properties. If the material is deformed with decreasing final rolling temperature after austenite formation, finer grains with high yield stresses are obtained by dynamic recrystallization (finely dispersed carbides are precipitated before, during, and after deformation). The yield stress increases with the cooling rate. Even with small additions of microalloying elements, this thermomechanical treatment leads to high strengths by a combination of grain refining and precipitation hardening.

Figure 220. Yield stress plotted against grain size at various austenitizing temperatures for a steel with ca. 0.1 % C, 1 % Mn, and 0.02 % Nb [344]

Pearlite is another microstructure that hinders the movement of dislocations and limits the extent of this movement. The relationship between the 0.2 % offset yield stress and the interlamellar distance follows a Hall – Petch equation [345]. In martensite, the most important effect is solid solution hardening due to the high content of dissolved carbon. The high dislocation density caused by the flip-over process is also effective [346]. The boundaries of twins or blocks in the martensite take over the role of the grain boundaries. In bainite both flip-over ferrite and carbides are present.

Figure 221. Development of cavities at precipitated particles or nonmetallic inclusions, leading to dimples on the fracture surface [351]

Figure 222. Scanning electron micrograph of a dimpled fracture

Similar considerations also apply to austenitic steels, but corrosion resistance must also be considered. A further possibility is the hardening of unstable austenitic steels by partial conversion to ε- or α'-martensite by prestraining, particularly at low temperature, and/or during loading [347].

The analysis of strength-increasing mechanisms is important because these mechanisms can affect toughness properties in various ways (Section 6.1.3.2). The attempt should always be made to choose a suitable combination of mechanisms.

Toughness and Fracture Behavior [304], [348–350]. *Fracture Characterization* [351–354]. When steel is in service, overloads that could eventually lead to fracture cannot be completely excluded. Not only strength, but also toughness is of great importance. For body-centered cubic steels, there are two different types of fracture: ductile fracture at high temperature, and brittle fracture at low temperature.

Figure 223. Scanning electron micrograph of a transcrystalline cleavage fracture

Ductile fracture takes place after plastic deformation caused by tensile stress, which can reach very high values in pure metals. In industrial materials, cavities form in the course of deformation before fracture. These start at the phase boundaries between the matrix and the inclusions or precipitates. They grow and coalesce as the load is applied (Fig. 221) [355], [356]. Typical cavities or dimples can be seen on the fracture surface, and the inclusions which led to the initiation of pore formation can often be an-

alyzed. A typical scanning electron micrograph of a dimple fracture is shown in Figure 222.

Brittle fracture (Fig. 223) takes place by transcrystalline separation of crystal faces when a critical tensile stress, the microscopic cleavage fracture stress, is reached. Macroscopic deformation cannot usually be detected. The test piece or component fails suddenly. If the grain boundaries are weakened by precipitates or concentrations of foreign atoms, intercrystalline cleavage fracture can occur by separation at the grain boundaries.

External Influences on Fracture Behavior. The most important external influences on fracture behavior are temperature, loading rate, and state of stress. The effects of temperature and loading rate are shown in Figure 224, in which the temperature – lower yield stress curve is shown as a continuous line. When the temperature is lowered, the level of microscopic cleavage fracture stress is eventually reached. This stress value is only slightly affected by temperature. Below the point of intersection, the material fails by brittle fracture. At higher temperatures, ductile fracture takes place; i.e., after the yield point has been exceeded, deformation, cavity formation, cavity growth, and fracture occur.

Figure 224. Effect of temperature on lower yield stress R_{eL} and cleavage fracture stress σ_f^* [357]

Figure 225. Effect of stress state on transition temperature [357]

At higher strain rates, the yield stress increases, but the cleavage fracture stress is almost unchanged. The transition temperature is shifted to higher values (Fig. 224), and the safe operating temperature is higher.

Figure 226. Effect of temperature on the behavior of test pieces and components that contain cracks [358]

The state of stress is important for fracture behavior, and this too can be shown by changes in cleavage fracture stress and yield stress. With multiaxial stress, ductile deformation begins as soon as the difference between the highest and lowest principal stress reaches the value of the yield stress (Tresca's flow criterion):

$$R_{eL} = \sigma_1 - \sigma_3$$

Figure 225 shows the effect of temperature on the highest principal stress σ_1; the following equation must always be valid at the onset of flow:

$$\sigma_1 = R_{eL} + \sigma_3$$

The fracture condition in the brittle fracture area is reached when the highest principal tensile stress is equal to the microscopic cleavage fracture stress:

$$\sigma_1 = \sigma_f^*$$

Because the stress is multiaxial, the brittle – ductile transition temperature is shifted to higher values. Multiaxial stresses in components tend to occur at notches and cracks, so fractures tend to start at these locations. Ahead of the notch or crack, a plastic zone always appears, as a principal stress on the free surface disappears. The plastic zone is larger for larger notch radii and lower yield stresses.

Figure 227. Effect of temperature on toughness [358]

It follows that a test piece or component that contains cracks has a characteristic behavior which depends on the testing temperature or operating temperature. At low temperatures, fracture takes place within the elastic part of the stress – strain curve, at low stress values and with small plastic zones as shown in Figure 226, which refers to an example of a center-notched flat tensile test piece [358]. With increasing temperature, the size of the plastic zone at fracture increases, until the whole section flows. As the temperature increases further, the fracture stress decreases as the yield stress decreases, but the mechanism of cleavage fracture remains. Ductile fracture occurs above the transition temperature T_i. Initially crack growth is stable, but soon reverts to unstable cleavage fracture. The effect of temperature on the onset of plastic deformation, ultimate strength, and fracture stress are also shown in Figure 226. Above T_a, stable crack growth takes place until the test piece is completely broken in two.

The corresponding figures for toughness are shown in Figure 227. The terminology is taken from the nomenclature of fracture mechanics, but the characteristic shape of the curve, with a lower plateau, a transition region, and an upper plateau is observed in all testing methods. The detailed form of the curve varies according to the shape of the test piece. Index i applies to the values at the beginning of stable crack growth, which cannot be determined with all test methods.

Test Methods [359–361]. Toughness measurements can be used to compare different steels, enabling product consistency to be monitored (quality control) or the effect of different microstructures to be observed (development of steel properties). In another group of test meth-

Figure 228. Test pieces and results of tensile tests to characterize toughness and fracture behavior [361]

ods, the results enable prediction of component behavior.

The result of a test can be expressed as a transition temperature which separates the brittle region from the ductile region. Alternatively, statements can be made about the degree of toughness, especially in the region of ductile fracture.

Testing methods can be divided into two groups. Small test pieces are prepared from the material being investigated, and tested at various temperatures or at the intended operational temperature. Large test pieces similar to the component can simulate operational conditions, and hence give more reliable predictions of the suitability of the material. Their use is very expensive, and is only justified for special applications; they are not described in detail here [303], [304].

Test piece shapes and the results of tensile measurements are illustrated in Figure 228. The reduction in area changes as the temperature moves from the lower plateau, characterized by brittle fracture, through the transition region to the upper plateau, with ductile fracture and stable crack growth. The lowest transition temperatures are obtained with smooth tensile test specimens at quasistatic loading rates. The transition to higher temperatures takes place on dynamically loaded notched test pieces.

Notch bending tests are of great practical importance (Fig. 229). The testing of a shape similar to that of the component (VAN DER VEEN)

Figure 229. Testing devices, test pieces and test results in notched bending tests [361] (dimensions in mm)

is shown, as well as various proposed notched impact bending tests. The ISO V-notched bar is used inernationally. The transition from the lower to the upper plateau can be seen by plotting the impact energy, or the amount of brittle fracture surface as a function of temperature. Increasing notch acuity increases the transition temperature.

Figure 230. Notch impact energy – temperature curves for various notch shapes for an unalloyed steel with ca. 0.22 % C and yield stress $\geq$ 255 MPa (St 42-2) (dimensions in mm) A) DVM U-notch test pieces; B) ISO V-notch test pieces

To give an idea of the scatter of the results, and hence of the accuracy of all the figures, Figure 230 A shows the effect of temperature on the impact energy for DVM (Deutscher Verband für Materialprüfung) U-notch test pieces and Figure 230 B shows results for ISO V-notch test pieces. In the brittle low-temperature region, the scatter of results is small. The greatest degree of scatter, in the impact energy at constant temperature or in the temperature shift at constant energy, occurs in the transition region. In the upper plateau, the scatter decreases. Most investigations on the effect of microstructure on toughness have been carried out by measuring notch impact toughness.

The effect of the state of stress on the transition temperature has been systematically investigated. Figure 231 shows that the transition temperature for very different types of steel increases linearly with the degree of multiaxiality, defined as the ratio of the equivalent stress (VON MISES) to the largest principal normal stress. It is possible to calculate the test results for test pieces with other notch acuities.

Sharp cracks produced by fatigue in the test pieces are used, according to the concept of fracture mechanics [363–367]. It is possible to state the stress in components that contain cracks, and in corresponding laboratory test pieces, with the same parameters. The characterization, carried out by means of the stress intensity, is of crack-tip opening displacement, or by the J-integral (Fig. 232). The stress intensity is thus a measure of the state of stress ahead of the crack. The crack tip opening displacement immediately gives the local elongation at the crack tip. The J-integral is a measure of the deformation energy required for plastic deformation of the crack tip. The original definition is derived from a path-independent line integral around the crack tip. In standardized approximation methods, the J-integral can be determined by laboratory investigations from the load – elongation diagram. Whereas the application of the stress intensity K is limited to linearly elastic properties, the concept of crack-tip displacement and of the J-integral can be used, with certain limitations, over the whole range from brittle to ductile behavior in the upper plateau. In the ductile fracture region, the onset of stable crack growth is characteristic (Fig. 233). The behavior on further loading can then be expressed numerically by a crack resistance curve, either as crack-tip opening displacement or as a J-integral, depending the stability of crack growth.

The effect of loading rate on toughness can be described quantiatively with the aid of test methods based on fracture mechanics [369]. Figure 234 shows the fracture toughness of FeE 460 steel as a function of temperature for various loading rates. In the lower plateau, the toughness values are almost independent of the load-

Figure 231. Effect of the degree of multiaxiality π on the transition temperature at $A_v \approx 40\,\mathrm{J/cm^2}$ with various shapes of notch impact test pieces of unalloyed steels with $\leq 0.16\,\%$ C (boiler plate HI), ca. 0.15 % C (Ck 15), ca. 0.22 % C (Ck 22), and ca. 0.35 % C (Ck 35)

Figure 234. Effect of testing temperature on fracture toughness at various loading (testing) rates for the steel FeE 460 referred to in Figure 211 [CT (compact tension) test specimens, 13 mm thick] [368]

ing rate, while in the upper plateau, the toughness increases with loading rate. In the transition region, increasing loading rate causes a considerable shift of the transition temperatures to higher values. This result is due to the sensitivity of the elastic limit and yield stress to the loading rate. With increasing loading rate, the yield stress increases, and the plastic zone ahead of the crack becomes smaller. The transition temperature varies linearly with strain rate sensitivity (Fig. 235) [370]. The quantitative relationship is given by the formula in Figure 212. The increase in the values at the upper plateau with increasing loading rate has been established by determining crack resistance curves at high loading rates [371], [372].

Because small test pieces are not suitable for determining the properties of actual components, and test pieces that simulate components are very expensive, safety concepts have been developed that use mathematical models based on fracture mechanics [367], [373]. The most accurate, but also the most elaborate of these is stress analysis, in which the method of finite elements is used to calculate the stress in the component, expressed as the crack-tip opening displacement or the J-integral, and compared with critical characteristic material parameters

determined in the laboratory. Increasing simplification leads to the EPRI method, the "two-criteria approach" or R6 method, and finally to the CTOD design curve of DAWES and BURDEKIN. The results are on the conservative side, and the discrepancies between these and the actual failure point increase with increasing simplification. For the use of these methods the fracture mechanical parameters of the material must be determined in every case.

Figure 235. Shift of the fracture toughness – temperature curve by dynamic loading as a function of the strain rate sensitivity of the flow stress of various steels [370]

Figure 236. Decrease of transition temperature of notched impact energy (T_t at 50 % of upper plateau) as a function of grain size for an unalloyed, fully killed steel with 0.19 % C, 0.27 % Si, and 1.46 % Mn (St 52-3) [375]

Effect of Microstructure [374]. Microstructure has various effects on toughness. These have an important bearing on the behavior of steels in use, and their suitability for certain applications.

Grain refining reduces the transition temperature (Fig. 236). Similar results have been found with other test methods. The effect of a finer grain is favorable, because it increases strength (see Fig. 213) and improves toughness, as measured by transition temperature. The explanation is that the microscopic cleavage fracture stress σ_{f*} is increased to approximately four times the yield point R_{eL}, so that the transition temperature for finer-grained material not only fails to increase, but is shifted to lower values (Fig. 224) [376], [377]. This useful effect of grain refining is utilized in all modern steelmaking processes, e.g., in fine-grained structural steels and in thermomechanical treatment.

Figure 237. Transition temperature of notch impact energy (T_t at 35 J/cm^2 with DVM test specimens) plotted against degree of deformation for various steels
Curve 1, fully killed constructional steel; 2, 3, unalloyed boiler plate; 4, 5, unalloyed fine-grained steels, normalized; 6, 7, alloyed fine-grained steels, normalized; 8 – 10, alloyed fine-grained steels, quenched and tempered; 11, 12, alloyed steels, tough at low temperature [378]

Figure 238. Effect of cold working due to increase in dislocation density on notched impact energy [379], [380]
A) Notch impact energy – temperature curve of an unalloyed, fully killed steel with ca. 0.15 % C, 0.4 % Si, and 1.4 % Mn (St 52-3); B), C) Effect of deformation degree on the transition temperature of hot-rolled wide strip of two unalloyed steels (Solid line = cold formed + aged, 250 °C, 30 min, air; Broken Line = cold formed); B) 0.14 % C, 0.1 % Al, and 0.006 % N (St 37-3); C) 0.08 % C and 0.009 % N (St 37-1)

Other processes for improving strength usually have unfavorable effects on toughness. The transition temperature increases with increasing cold working for many steels investigated. A deformation of 10 % increases the transition temperature by 20 – 30 K (Fig. 237). The effect on fracture mechanics tests can be even greater.

If cold working is combined with an aging treatment, (e.g., annealing at 250 °C with air cooling) a further shift of the transition temperature takes place by an amount that depends on the grade of steel. Figure 238 A shows the effect of temperature on the notch impact energy for various degrees of deformation. The change in the transition temperature caused by cold working alone, and the effect of an additional aging on a killed steel (Fig. 238 B) and a rimming steel (Fig. 238 C) are also shown. The considerably greater effect of strain aging on rimming steel can be seen. This is due to the higher content of free nitrogen. Figure 238 shows that, in the discussion of the sensitivity to aging of steel, the distinction must always be made between the effect of cold working alone (which always leads to an increase in the transition temperature) and that of additional aging (the magnitude of which depends on the level of dissolved nitrogen and/or carbon).

If the increase in yield stress is achieved by precipitation, toughness is usually decreased. This is also true for pearlitic structures in which increased pearlite content causes a decrease in the upper plateau and an increase in transition temperature.

Figure 239. Effect of an increase in yield stress caused by various influences on the transition temperature of the notch impact energy [381]
a) Solid solution hardening by carbon; b) Strengthening by dislocations; c) Precipitation hardening; d) Solid solution hardening by manganese and nickel; e) Grain refining

Figure 240. Contribution of grain refining and precipitation hardening to:
A) Change in yield stress; B) Change in transition temperature of notch impact energy (toughness)Unalloyed, fully killed steel, ca. 0.15 % C, 0.4 % Si, and 1.4 % Mn (St 52-3) with 0.05 % Nb, 0.1 % V or 0.1 % Ti [382]

Figure 239 gives a summary of the results, which show the relationship between increase in yield stress and change in transition temperature. Only grain refining (e) causes a significant reduction, i.e., improvement, in the transition temperature, with a simultaneous increase in yield stress. The other mechanisms of strength improvement increase the transition temperature. The effect of Mn and Ni is probably explained by transformation behavior leading to a secondary microstructure that is more finely grained.

Figure 240 shows the important relationship between the amount of added Nb, V, or Ti and the yield stress for the development of microalloyed fine-grained structural steels [331], [382]. In Figure 240 A, yield stress is plotted against the reciprocal of the square root of grain size, which should give a straight line according to the Hall – Petch equation for grain refining (see also Fig. 220). The yield strength is most effectively increased by the addition of Nb, which causes grain refining and also hardening (to ca. 200 MPa). Titanium and vanadium are less effective grain refiners. Figure 240 B shows the effect on the transition temperature. Although the addition of Nb causes grain refining and hence hardening, it also causes a reduction, i.e., an improvement, in the transition temperature. Vanadium leads to less grain refining and a less favorable transition temperature. Titanium occupies an intermediate position.

The diagram, which has been extended by many other investigations, shows that microalloying elements have various effects. A suitable combination of alloying elements can be used, depending on rolling conditions and intended operational conditions.

Accompanying elements in steel also affect its toughness properties. Sulfur is picked up from the coke in the blast furnace, but most is removed by the blast furnace slag and in the steelworks. The remaining amount (<0.02 %) leads to some deterioration of the toughness properties. Sulfur is practically insoluble in iron in the solid state and, at room temperature, is present as the sulfide, but mainly as MnS in structural steels. The sulfides are deformed during hot rolling, and mainly affect the toughness properties in the upper plateau. Figure 241 shows the relationship between the rolling conditions and the results of notch impact tests with various test piece orientations. These can be explained by assuming that the interface between the matrix and the inclusions promotes the fracture. An increase in the degree of deformation affects the differences in the direction of stress by extension of the sulfides. This is also shown in Figure 242, which shows the effect of sul-

Figure 241. Relationships between notch impact energy, shape of sulfides, orientation of the test piece, and degree of deformation for various ratios of stretch to spread

fur content and that of desulfurization by CaSi treatment. This treatment not only reduces the sulfur content to $< 0.004\,\%$, but also increases the sulfide hardness, which reduces the stretching of the sulfide. The effect on the anisotropy is shown in Figure 243 A, which presents the notch toughness – temperature curves for longitudinal, transverse, and through-thickness test pieces taken from thick steel plate of conventional manufacture; the corresponding curves in Figure 243 B show considerably higher values in the upper plateau and an almost isotropic behavior after treatment with CaSi.

Sulfides have similar effects on the reduction in area in the thickness direction. Figure 244 shows typical values for the reduction of area when breaking FeE 355 steel plate in the thickness direction. It can be seen that the most frequent value of 13 % (for sulfur content 0.015 – 0.054 %) is increased to 68 % after treatment with CaSi, and the scatter of results is considerably reduced.

Phosphorus also has an unfavorable effect on toughness, mainly because of segregation at the grain boundaries. Figure 245 shows the transition temperature corresponding to 50 % ductile fractures in notch tests for 20MnMoNi55 steel as a function of phosphorus content. However, investigations have shown that phosphorus has hardly any effect on the toughness of thick (40 mm) FeE 355 steel plate. Notch impact energy – temperature curves for transverse test pieces with phosphorus content 0.002 – 0.13 % are compared in Figure 246.

Microstructures with Optimal Combinations of Strength and Toughness [388–391]. For an optimum combination of strength and toughness, particular attention must be paid to the values in the upper plateau or the transition temperature region, depending on the intended use. Figure 247 A shows the effect of various alloying elements on yield stress and transition

temperatures; Figure 247 B shows the effect of precipitation hardening and grain refining. Grain refining has a beneficial effect on both yield stress and transition temperature, whereas the other strength improvement mechanisms increase the transition temperature. If the transition temperatures are plotted against the yield stress, the connection between toughness and strength can be seen in zones corresponding to the various steel microstructures (Fig. 248).

Figure 245. Effect of phosphorus on toughness of 20MnMoNi55 steel [386]

Favorable transition temperatures can be achieved by thermomechanical treatment with constant strength, or, conversely, the strength can be higher for constant transition temperature. Further optimization is possible by producing a bainitic structure, albeit at higher alloying cost, as the transformation is usually promoted by the addition of ca. 0.3 % Mo. Tempering steels show the best combination of properties, but the cost of the alloy and of the tempering process must be considered.

Figure 249 shows how the systematic development of steel products and their thermomechanical treatment has enabled steels with yield strengths up to 650 MPa and transition temperatures of $-80\,^{\circ}C$ to be produced, although these are only laboratory-scale investigations.

6.1.2.1.2. Behavior Under Cyclic Loading

Reverse Strain (Bauschinger Effect) [392]. If, after an initial forming operation in a certain direction, the direction of forming is reversed, flow begins at lower stress (Bauschinger effect) [393]. Figure 250 shows the result of reversal of the forming direction for various steels. Figure 250 A shows work hardening of the materials St 37-3, C 35, and C 70 under tensile load. If the stress direction is reversed after a given amount of prestrain, values of the crushing yield

point $\sigma_{q0.2}$ (shown by a continuous line) are obtained. Even for small amounts of prestrain, the crushing yield point decreases steeply, and then slowly begins to increase. The effect increases with increasing carbon content. After low-stress annealing, $R_{p0.2} \approx \sigma_{q0.2}$. Figure 250 B shows prestrain by compression, followed by a tensile test.

The Bauschinger effect is due to internal (residual) stresses. In single-phase materials, stresses are formed between dislocations, and these favor movement in the opposite direction. In polycrystalline or multiphase materials, internal stresses are produced between parts of the microstructure with different strength properties. The directions of these are such that they also reduce the stress of deformation in the reverse direction.

Cyclic Loading (Fatigue) [394–397].
When very frequent reversals of stress take place in metallic materials, irreversible changes occur if the stress maxima lie appreciably below the yield point. As the number of oscillations increases, cracks begin to form. After these have grown to some extent, fracture occurs. Typical

types of stress are illustrated in Figure 251, and the results are shown in Figure 252, an extended Wöhler diagram. The number of oscillations is increased at various amplitudes, until the first strain structures appear, i.e., permanent damage begins, leading eventually to fracture. Below the fatigue strength, no failure takes place, even with a high number of oscillations, and no traces of deformation are observed below the fatigue limit. In steels with well-defined yield points, there are irreversible changes in the phase which is free of incipient cracks. The permanent elongations after oscillating stress are usually considerably less than those found by tensile tests, as individual dislocations become separated from their Cottrell atmosphere, enabling Lüders bands to develop.

Figure 248. Yield stress and transition temperature of notch impact energy of steels of different microstructure [331]

Figure 249. Mechanical properties of hot-rolled wide strip of unalloyed and microalloyed steels of different microstructure [331]
T_{35} = temperature at which the notch impact toughness decreases to 35 J/cm^2; ISO V-notch test specimens

As soon as macroscopically detectable cracks appear, the rate of crack growth follows the Paris law:

$$\mathrm{d}a/\mathrm{d}n = C\,(\Delta K)^{\mathrm{m}}$$

where da/dn is the crack propagation rate, ΔK the stress intensity amplitude, and C and m are constants. This relationship is shown in Figure 253. The crack growth rate lies within a common scatter band for many steels (Fig. 254) if corrosive effects are excluded.

The fatigue strength is proportional to the tensile strength. For tension/compression, reversed symmetric stress applies:

$$0.3 < \sigma_{\mathrm{zdW}}/R_{\mathrm{m}} < 0.45$$

Alloying elements have a similar effect on fatigue strength as on tensile strength. Figure 255 shows their effect on tensile strength R_{m}, and their effect on fatigue limit under reversed bending stresses σ_{zdW}. Purity is of great importance for fatigue strength, as cracks usually start at inclusions just below the surface. Thus, electroslag or electron-beam-melted materials have enabled the fatigue strength of roller bearing steels to be increased considerably [403]. Prestraining increases the fatigue strength if the deformation is greater than the Lüders elongation.

When evaluating components subjected to cyclic stress, the sequence of stresses is very important. Statistical analysis of the stress enables simulation of a fatigue test of a component under operational stress [394], [404]. The sequence effect is a result of the plastic zones and the internal compression stresses which they cause ahead of the crack tip. These slow down further crack growth at higher amplitudes.

6.1.2.1.3. Behavior at Higher Temperatures [405], [406]

In the range between room temperature and ca. 400 °C, interactions between interstitially dissolved carbon or nitrogen atoms and dislocations lead to dynamic strain aging, which causes jerky flow during plastic deformation in the tensile test (see Fig. 207). If the yield points for various elongations are read from this diagram and plotted against temperature, the curve shown in Figure 256 is obtained. Dynamic strain aging

Figure 250. Plots of 0.2 % compression limit ($\sigma_{q0.2}$) and 0.2 % proof stress ($R_{p0.2}$) as a function of the extent and direction of strain before and after stress-relief annealing of various unalloyed steels [393]
A) Prestrain by tension; B) Prestrain by compression

increases the resistance to plastic deformation, and the material is hardened, especially in the medium-deformation range. The toughness decreases (blue brittleness). The maximum interaction is shifted to higher temperature with increasing strain rate [407].

In hot forming, hardness is reduced during or after the forming process, by dynamic or static recrystallization [408]. Changes in yield stress can be determined, e.g., by hot-torsion tests. Figure 257 shows how the yield stress changes with deformation temperature for strain

Figure 251. Ratios of mean stress to stress amplitude under cyclic loading [398]
σ_m = mean stress = static prestress; σ_a = stress amplitude; σ_{max} = maximum stress; σ_{min} = minimum stress

values of 0.05, 0.2, and 0.4, at various deformation rates. The yield stress decreases rapidly with increasing temperature, and at the transition from the body- centered to the face- centered cubic structure, an intermediate maximum occurs. Figure 258 shows flow curves at 1100 °C. After an initial hardening, the strength decreases by recrystallization until a stationary state with an approximately constant yield strength level is reached. Repeated changes from hardening to softening can lead to periodic curves.

Figure 252. Extended Wöhler diagram [399], [400]

Figure 253. Effect of amplitude of stress intensity ΔK on crack propagation rate d*a*/d*n* [401]

If steel is stressed at high temperature for long periods, creep can take place, i.e., time-dependent deformation at constant stress [406]. Figure 259 A shows that the strain rate is initially high, and then constant. Toward the end of the experiment, there is an acceleration in the creep rate due to void formation and cross-sectional weakening. At higher stresses and temperatures, the phenomena occur more rapidly. Figures 259 B and C show a way of interpreting the creep curves for practical cases. Values for the stress and stress duration are used, leading to a figure for the elongation, or to fracture. This gives the maximum tolerable stress for a given component lifetime. Figures 259 D and E show a method of analyzing mechanical operations. Figure 259 D shows a plot of the logarithm of the strain rate against the logarithm of the strain. A region of constant strain rate, stationary creep, can be seen. If the strain rate is plotted against the stress on a log – log scale, a straight line is obtained which satisfies the equation $\sigma = \varepsilon^n$. This creep law enables the activation energy to be determined from measurements over a range of temperature [411].

Figure 254. Effect of amplitude of propagation stress intensity ΔK on crack propagation rate d*a*/d*n* for a series of steels with very different chemical compositions and with yield stress 250 – 1680 MPa [363], [401]

Figure 255. Effect of alloying elements on tensile strength and fatigue limit under reversed bending stress of pure iron [402]

The microstructure must be stable in hot-strength steels. Special carbides that contain molybdenum, chromium, or vanadium coagulate much more slowly than cementite, as the alloying elements also need to diffuse. This explains the principle underlying the alloys used for hot-strength steels, e.g., 15Mo3, 13CrMo4, and 14MoV63. A further increase in hot strength can be obtained with austenitic steels, as transverse slipping processes (which reduce the dislocation density and hence the strength) are hindered owing to the lower stacking fault energy.

Figure 256. Effect of temperature on yield stresses for elongation $\varepsilon = 10\,\%$, $20\,\%$, and $30\,\%$, lower yield stress R_{eL}, and Lüders strain, derived from Figure 208 [320]

Creep curves of a hot-strength austenitic steel at 700 °C under various tensile stresses are shown in Figure 260 A. The interpretation in Figure 260 B shows creep limit and creep stress rupture curves. Creep stress rupture curves are determined at various temperatures (Fig. 261). The shape of these curves, which drop away, explains why extrapolation to longer times is difficult. There is also a scatter in the results associated with the materials and the test methods used. It is therefore very difficult to predict results at high temperatures and long times from tests at low temperatures and short times. Elab-

Figure 257. Yield stress as a function of the deformation temperature for various deformation rates and degrees of deformation [409]

orate and prolonged tests must be carried out to predict creep behavior with confidence.

Figure 258. True stress – strain curves of a steel with 0.25 % C, deformed at 1100 °C in a hot-torsion test, i.e., in the austenitic state [410]

Steels, including austenitic steels, can be used at temperatures up to 800 °C, depending on operating conditions. Higher temperatures require the use of superalloys based on nickel or cobalt, sometimes strengthened by dispersed or fibrous materials. Ceramics provide an alternative approach.

The many varieties of steel show a broad spectrum of properties, determined by their microstructure. By the use of appropriate alloys, forming operations, and heat treatments, combinations of properties can be produced which place steel among the most important materials of modern technology. Examples of its use are given in Section 6.2.

6.1.2.2. Chemical Properties

6.1.2.2.1. Introduction

Iron is the most widely used metallic material and, alloyed with different elements, it is the basis of a wide variety of steels, with a range of mechanical properties and chemical stability. Iron itself is rather reactive, readily forming oxides, hydroxides, sulfides, etc. It undergoes an electrochemical reaction with humid air (rusting) which can rapidly consume unprotected unalloyed steel. The rust layer is not protective, unlike the thin, dense oxide layer on aluminum or zinc, but similar behavior can be attained by alloying Fe with Cr (> 12 % Cr gives stainless steels).

Iron is also very susceptible to oxidation or sulfidation at high temperature; FeO and FeS show a wide homogeneity range, correlated to high concentrations of lattice defects (cation vacancies), high diffusivities in the lattice, and high growth rates. Alloying can lead to high oxidation resistance; Cr steels or Ni – Cr steels with ca. 20 % Cr can be used up to 1000 °C, and Fe – Cr – Al alloys at even higher temperatures, since they form slow-growing oxide layers, which also give limited protection in environments which are sulfidizing, carburizing, or chloriding (heat exchangers in combustion or gasification atmospheres).

The chemical behavior of iron and steels is of greatest interest in connection with corrosion problems (→ Corrosion); in the following, reactions and corrosion processes are described only briefly, emphasizing the special points of chemical behavior of iron and steels.

6.1.2.2.2. Uniform Corrosion

Corrosion of iron in aqueous electrolytes results from the anodic dissolution process:

$$Fe \longrightarrow Fe^{2+} + 2e^- \tag{6.1}$$

and the simultaneous, independent cathodic reduction of an oxidizing agent, in most cases either hydrogen ions:

$$2\,H^+ + 2\,e^- \longrightarrow 2\,H_{ad} \longrightarrow H_2 \tag{6.2}$$

or oxygen molecules dissolved in the electrolyte:

$$(O_2)_{aq} + 2\,H_2O + 4\,e^- \longrightarrow 4\,OH^- \tag{6.3}$$

The potential dependence of reactions (6.1) and (6.2) is described by the Volmer – Butler equation, an exponential relation; oxygen reduction is mostly controlled by diffusion of molecular oxygen to the metal surface, independent of potential. The overlap of anodic and cathodic reactions is shown in Figure 262. The corrosion potential U_k is established at a negative value,

Figure 259. Interpretation of creep tests at constant temperature
Relationships between strain ε, strain rate $\dot{\varepsilon}$, time t, and stress σ [406]
A) Time – strain curves at constant stresses; B) – F) Evaluations of these curves

where the current density of anodic dissolution i_a and oxygen reduction i_k are equal. The anodic dissolution is further dependent on the concentration of defects in the metal surface, and especially for iron, is enhanced with increasing concentration of OH^- [413], and also SH^- or NH_4^+ [414].

Figure 260. Evaluation of creep tests at 700 °C on a high-temperature austenitic steel with ca. 0.12 % C, 20 % Co, 21 % Cr, 3.2 % Mo, 20 % Ni, and 2.5 % W (X12CrCONi2120) [412]
A) Creep curves; B) Creep limit and creep stress rupture curves

The reduction of H^+ occurs in several steps; electron transfer occurs by the Volmer reaction:

$$H^+ + e^- \longrightarrow H_{ad} \tag{6.4}$$

The adsorbed H_{ad} atoms can react to H_2, according to the Tafel reaction:

$$2\,H_{ad} \longrightarrow H_2\,(g) \tag{6.5}$$

or the Heyrowski reaction:

$$H_{ad} + H^+ + e^- \longrightarrow H_2\,(g) \tag{6.6}$$

Adsorbed H atoms also can enter the metal, which leads to hydrogen-induced cracking (HIC) or hydrogen-induced stress corrosion cracking (HISCC).

Figure 261. Creep stress rupture curves of a high-temperature Cr – Ni steel at various test temperatures [412]
a) 600 °C; b) 650 °C; c) 700 °C; d) 800 °C

Figure 262. Electrochemistry of iron corrosion

In neutral water, the corrosion rate is determined by H^+ diffusion to the metal surface, and the anodic dissolution rate is restricted to 0.2 µA/cm^2, corresponding to 2×10^{-4} cm/a. Since the exchange current densities i_0 of the Volmer and Tafel reactions are very low, and since that of the Heyrowski reaction is negligibly small [415], iron does not corrode in neutral water free of oxygen. In contrast, the corrosion of iron in neutral water saturated with oxygen (in equilibrium with air) is rapid – the calculation assuming rate- controlling O_2 diffusion in a slowly flowing electrolyte yields 0.15 mA/cm^2, corresponding to a corrosion loss of 0.15 cm/a. This high value is not reached under natural conditions, since rust is formed, and the oxygen must diffuse through the pores of this corrosion product.

6.1.2.2.3. Atmospheric Corrosion

In corrosion by oxygen- containing electrolytes, Fe^{2+} is oxidized to Fe^{3+}, and oxides and oxyhydrates are precipitated on the metal surface:

$$4\,Fe^{2+} + 3\,O_2 + 2\,H_2O \longrightarrow 4\,FeOOH \qquad (6.7)$$

$$6\,Fe^{2+} + O_2 + 12\,OH^- \longrightarrow 2\,Fe_3O_4 + 6\,H_2O \qquad (6.8)$$

These reactions occur on the surface of the solid corrosion products and not in the electrolyte. Atmospheric corrosion (rusting) in the presence of a liquid electrolyte film [416] on the metal leads to Fe_3O_4 at the iron surface, and FeOOH and Fe_2O_3 at the phase boundary with the atmosphere. With restricted oxygen access, when all pores of the rust are filled with water, Fe^{2+} formed at the inner phase boundary [417] can react with FeOOH:

$$Fe^{2+} + 2\,FeOOH + 2\,OH^- \longrightarrow Fe_3O_4 + 2\,H_2O \qquad (6.9)$$

On drying the rust layer, allowing better access of oxygen, Fe_3O_4 is oxidized again to FeOOH. Atmospheric corrosion can be retarded by certain alloying elements: Cu, P, Cr, and Ni, which are added to rust-resistant steels, e.g., Corten. Sulfur dioxide strongly accelerates rusting of steels by initiating the reaction sequence [418]:

$$4\,Fe + 4\,SO_2 + 2\,O_2 + 4\,H_2O \longrightarrow 4\,FeSO_4 + 4\,H_2 \qquad (6.10)$$

$$4\,FeSO_4 + 6\,H_2O + O_2 \longrightarrow 4\,FeOOH + 4\,H_2SO_4 \qquad (6.11)$$

In this reaction sequence, one SO_2 molecule can transfer 15 – 150 Fe atoms into the rust [419] by its catalytic action, until the reaction is stopped by formation of insoluble basic iron sulfates.

6.1.2.2.4. Passivation

The passivation behavior of iron is shown in Figure 263 [420]. In region 1, the current – potential curve describes active anodic dissolution; according to the Butler – Volmer equation, the increase in current is exponential. In region 2, the increase is limited since the solubility limit of $FeSO_4$ is approached at the metal surface – corrosion is controlled by outward diffusion of the Fe^{2+} through the diffusion boundary layer, independent of potential. At the passivation (Flade) potential U_F the current density abruptly decreases, owing to formation of a passive layer, i.e., a very thin oxide layer, most probably γ-Fe_2O_3 [421], a few nanometers thick, depending on potential and temperature. In the passive region 3, a steady state of continuous film growth and dissolution is established, at current density i_p ca. 10^{-5} A/cm^2, corresponding to a corrosion rate 0.1 mm/a. In the transpassive region 4, enhanced iron dissolution and oxygen formation occur simultaneously. For the passivation potential of iron in the acidic region (in V):

Figure 263. Electrochemistry of passivation of iron in HCl 1 mol/L at 25 °C
U_T = transpassivation potential

$$U_F = 0.5 - 0.005\,pH \qquad (6.12)$$

Iron is passivated at pH > 10 by oxygen in the electrolyte, this is important for the use of reinforcing steel in concrete, because the electrolyte in the pores of the concrete is saturated with $Ca(OH)_2$ at pH 12.5. Iron can also be passivated in strong oxidizing acids such as HNO_3.

The current – voltage curve for nickel [422] is similar to that for iron; for chromium [423] the passivation potential is shifted to more negative potentials, and current density in the passive state is $< 10^{-7}$ A/cm^2 (Fig. 264). In the passive region, Cr^{3+} is formed and very slowly dissolved, in the transpassive region, formation of chromate and dichromate with hexavalent Cr begins. This behavior is reflected in the passivation of Fe – Cr and Fe – Ni – Cr steels [424]; with increasing Cr content the passivation potential is shifted to lower values and the current density in the passive region is decreased, so stainless steels are passive over a wide range of conditions. The breakthrough potential at which Cr^{6+}

formation starts, is virtually independent of Cr content.

Figure 264. Electrochemistry of iron passivation at various concentrations of Cr and Ni

6.1.2.2.5. Pitting Corrosion

If a passive layer is destroyed locally, the layer may heal under passivating conditions or, in the presence of halide ions, pitting may occur, i.e., local attack with formation of hemispherical pits. During pitting, active and passive regions are stable in the immediate neighborhood. The active areas are stabilized by the potential drop, caused by a high dissolution current through the electrolyte in the pit (the bottom of the pit is at potentials below passivation potential and the surrounding passive film is at a higher potential) [425]. Pitting occurs if the value of the pitting potential U_p is exceeded, and if the corrosive ions have a critical concentration c_L. For Fe – Cr and Fe – Ni – Cr steels, the pitting potential increases with Cr and Mo content (Mo is more effective than Cr). Since then, N has been found to be even more effective [426]. Pitting can start in Cr-depleted zones, e.g., after carbide precipitation at grain boundaries [427].

6.1.2.2.6. Crevice Corrosion

If there are crevices between a metal and a second phase, or in the metal itself, the onset of corrosion is often observed in the crevice, owing to retardation of the electrolyte exchange into and out of the crevice. When the transport of oxidizing agent into the crevice is retarded, leading to depletion of, e.g., dissolved oxygen, the potential may fall below the passivation potential and iron and low-alloy steels may start to corrode. Also, the transport of corrosion products out of the crevice is inhibited, and their hydrolysis may lower the pH, e.g., by the reaction:

$$Cr^{3+} + 3\,H_2O \longrightarrow Cr(OH)_3 + 3\,H^+$$

The increasing acidity reduces the activation and pitting potentials, so active corrosion or pitting may start [428], [429].

6.1.2.2.7. Intergranular Corrosion of Stainless Steels

Ferritic chromium steels and austenitic Cr – Ni steels are susceptible to intergranular corrosion after sensitization, i.e., after precipitation of carbides at 450 – 750 °C. Precipitation at grain boundaries [430], [431] leads to chromium depletion nearby. If the potential is in the range between the passivation potentials of the steel and iron, rapid dissolution of the metal phase occurs along the grain boundaries. Potentials in this range are established in the Strauss test [432], where the sample is in contact with Cu and immersed in $CuSO_4 - H_2SO_4$ solution, so that sensitized materials undergo intergranular disintegration. In the temperature – time diagram, the conditions for sensitization are limited by curves for the onset of carbide precipitation, which tends to shorter times at higher C concentration and longer times at lower temperature, and by curves for the end of carbide precipitation, which also needs shorter times at higher temperature. After the end of precipitation, the chromium concentration equalizes and the material becomes corrosion resistant again.

This intergranular corrosion of stainless steels can be suppressed by very low carbon concentrations < 0.01 % (Fig. 265), or by addition of stabilizing elements, such as Ti and Nb, which tie up carbon in very stable carbides [433], [434]. Precipitation of TiC and NbC can be induced by heat treatment at 900 – 950 °C (stabilization), where the chromium carbides dissolve and the solubility of TiC and NbC is still very low; such treatment is important after welding of steels.

a) 0.04 % C; b) 0.02 % C; c) 0.01 % C

6.1.2.2.8. Stress Corrosion Cracking

The preconditions for stress corrosion cracking (SCC) are: (1)

the stress causes a shear or strain of the material; and (2)

the electrolyte induces formation of a passive or protective layer [435], [436]. The strain leads to failure of the passive layer at a slip step; there the free material is rapidly attacked under anodic dissolution. Repeated failure at this spot initiates crack growth. The electrolyte forms a new protective film at the walls of the crack and only the crack tip stays active, leading to deep cracks. Strain rate and passivation rate must obey certain relations to obtain SCC; if, for example, the passivation rate is too high, this leads to immediate passivation of the whole crack and termination of crack growth, whereas too slow passivation leads to strong truncation of the crack, or widening to a deep groove. SCC is observed in the following cases:

1) Austenitic steels in chloride solutions – transgranular crack growth [437–441]
2) Ferritic and ferritic – pearlitic structural steels in hot concentrated alkali carbonate and nitrate solutions – intergranular crack growth [442–446]

The latter type of SCC is enhanced by the presence of impurity elements, such as P, at grain boundaries, similar to the intergranular corrosion of iron and ferritic steels in nitrates at elevated potentials [446]. Under stress conditions, the selective corrosion of the crack tip causes SCC at low P concentrations and without anodic polarization.

6.1.2.2.9. Hydrogen Adsorption and Hydrogen Embrittlement

On the surface of iron or steel, immersed in aqueous solution, the interplay of reactions (6.1) – (6.6) establishes coverage with adsorbed hydrogen H_{ad}, which may correspond to a high hydrogen activity ($a_H = 1$ at $p(H_2) = 100$ kPa), depending on electrochemical potential E and pH:

$$\log a_H = E\frac{F}{2.3RT} + \mathrm{pH} = \frac{E}{0.059} + \mathrm{pH} \qquad (6.13)$$

especially if the Tafel reaction (6.5) is poisoned by inhibitors, such as arsenic acid in the electrolyte. In a neutral NaCl solution free of oxygen, the corrosion potential E of iron is -0.6 V, and hydrogen activity can reach 10^3. Correspondingly, hydrogen is absorbed into the iron matrix in much higher concentration than its solubility at $p(H_2) = 100$ kPa, which at 25 °C is ca. 3 atoms per 10^8 iron atoms [447], [448]. Not all hydrogen in steels is dissolved, i.e., distributed on interstitial sites; most is in special sites (traps) where its energy is decreased, owing to stress fields in the lattice around dislocations, inclusions, etc. [449]. High hydrogen concentration in steels causes hydrogen embrittlement, i.e., decrease of toughness and brittle fracture. This effect of hydrogen is explained by H enrichment at the crack tip, where it weakens the Fe – Fe bonds in the already strained regions at the tip, and decreases the surface energy of the newly formed surface in the crack [450]. By this mechanism the presence of hydrogen can cause hydrogen-induced cracking (HIC), and aggravate stress corrosion cracking (HISCC). High-strength steels are especially susceptible (→ Corrosion).

6.1.2.2.10. Oxidation of Iron

Iron forms three oxides, hematite Fe_2O_3, magnetite Fe_3O_4, and wustite FeO which is stable only above 570 °C [451–453]. FeO has a wide range of homogeneity, due to cation vacancies V_{Fe}^{2-}, for which the concentration is dependent on oxygen pressure. Oxidation of iron at temperatures > 570 °C yields fast-growing oxide layers composed of an outer layer of Fe_2O_3, then

Fe_3O_4, and a thick inner layer of FeO [454], [455]. The oxides grow mainly by outward diffusion of iron via cation vacancies, which move inward. Since the cation vacancy concentration is highest in FeO, the diffusivity of Fe^{2+} is high, and the growth rate is most rapid.

Owing to the high oxide growth rate, unalloyed steels cannot be applied at temperatures $> 570\,°C$, but perform reasonably well at lower temperatures, since the scale of hematite and magnetite grows slowly enough. In CO_2-CO and H_2O-H_2 mixtures at high temperatures, oxygen partial pressures are effective at which only FeO or a Fe_3O_4/FeO layer is formed. Under such conditions, the growth rate of FeO up to a thickness of about 100 µm is controlled by the phase boundary reaction on the outer surface [456–458], where the oxygen is transferred from the gases:

$$CO_2 \longrightarrow CO + O_{ad} \tag{6.14}$$

$$H_2O \longrightarrow H_2 + O_{ad} \tag{6.15}$$

In this stage of oxidation, a linear rate law applies for the increase of scale thickness:

$$\frac{dx}{dt} = k_1 \tag{6.16}$$

where the linear rate constant k_1 is a function of the partial pressures, the oxygen activity at the surface, and the distance from equilibrium [458–460]. There is a gradual transition from phase boundary reaction control to diffusion-controlled growth, where the rate is inversely proportional to the thickness x:

$$\frac{dx}{dt} = \frac{k_p}{x} \tag{6.17}$$

This results in the parabolic law:

$$x^2 = 2k_p t \tag{6.18}$$

which leads to growth rate decreasing with time. Such parabolic behavior is characteristic of most metals and alloys used at high temperatures, the lower the value of k_p the slower the growth of the scale. Values of k_p can be deduced according to the theory of C. Wagner [461] from data on the diffusivities of cations and anions or electric conductivity and transference numbers of the ions.

6.1.2.2.11. Oxidation of Carbon Steels and Low-Alloy Steels

On heat treatment and hot rolling, steels are oxidized and decarburized [462–464]. Oxidation is described by a linear law in CO_2 and a parabolic law in O_2; both reactions behave additively. At first only iron is oxidized and carbon is enriched in the metal below the scale. With continued scale growth, vacancies condense at the interface to form voids in which CO_2 and CO are formed in equilibrium with FeO. This gas diffuses outward through cracks and pores of the scale, which leads to carbon loss. Carbon diffusion through the solid oxide is impossible. After some time, a steady state is established in which the carbon supply to the interface is controlled by diffusion in the metal. Thus, after a brief oxidation, carbon enrichment is observed, but after long-term oxidation, the steel is always decarburized.

Some other more noble alloying (or impurity) elements in steels, e.g., Ni, Co, Cu, Sn, Pb, As, and Sb also enrich beneath the scale during oxidation. Enrichment of Cu, Sn, As, or Sb decreases the melting point, which can lead to difficulties in hot rolling. Specifically Cu, sometimes in combination with Sn, causes "hot shortness" by formation of a melt which penetrates into grain boundaries. If other elements are enriched beneath the scale, the iron must diffuse through this zone to the oxide – metal interface before it is oxidized. Especially for Fe – Ni and high-Ni steels [465–467], this causes inward growth of protrusions from the oxide into the metal which leads to a rugged, strongly interlocked interface; the oxide scale is strongly adherent to the metal and difficult to remove, e.g., after hot rolling. With increasing Ni content, enhanced temperature and oxygen partial pressure, the formation of FeO on Fe – Ni alloys is suppressed in favor of the more slowly growing spinel $(Fe,Ni)_3O_4$.

6.1.2.2.12. High-Temperature Steels

Steels to resist heat and oxidation must be alloyed with sufficient concentrations of Cr and/or Al. The slowly growing oxides Cr_2O_3 or Al_2O_3, which have a small degree of disorder, can form a protective scale. Iron – chromium alloys are the

base materials for many ferritic steels. The oxidation behavior as a function of Cr content is shown in Figure 266 [468]. At Cr concentrations $< 2\,\%$, the oxidation rate is increased since dissolution of Cr_2O_3 in FeO may even increase the amount of cation vacancies (Wagner – Hauffe doping effect); trivalent Cr replaces divalent Fe, this is equalized by negatively charged vacancies. With increasing Cr content wustite formation is suppressed, the spinel $(Fe,Cr)_3O_4$ is formed, for which the growth rate decreases with Cr content. At Cr content 15 –30 %, the mixed oxide $(Fe,Cr)_2O_3$ is formed on the metal surface, its growth rate shows a minimum at 20 – 25 % Cr in the alloy [469]. Many ferritic steels have Cr content 17 – 25 %; they are oxidation resistant, but there may be chromium depletion beneath the scale, and if the scale is damaged outgrowth of wustite may occur with formation of "rosettes."

Figure 266. Oxidation kinetics as a function of Cr content a) 1200 °C; b) 1100 °C; c) 1000 °C; d) 900 °C

This effect is suppressed in the Cr – Ni steels where, instead of wustite, a Fe,Ni spinel is formed. Such austenitic steels, with 20 – 27 % Cr and 12 – 32 % Ni, are widely used for high-temperature processes, since, in contrast to ferritic Fe – Cr steels, they have higher mechanical strength and do not show embrittlement by σ-phase formation. Additional alloying with 1 – 2 % Si improves resistance to oxidation and especially carburization, since an inner film of SiO_2 below the Cr_2O_3 retards oxidation and carburization.

Iron – aluminum alloys need 6 – 8 % Al to form a protective Al_2O_3 layer [470], [471], but only at temperatures $> 900\,°C$ is the most protective α-Al_2O_3 generated. Formation of Al_2O_3 and suppression of internal oxidation is favored by chromium; Fe – Cr – Al alloys with ca. 20 % Cr and 4 – 5 % Al are used for heating elements and other highly oxidation-resistant components. The lifetime of the heating elements is greatly increased by small additions of rare earths, e.g., Ce, Y, La, which strongly improve the adherence of the Al_2O_3 scale. The use of such additives also helps to improve other high-temperature alloys, in terms of nucleation, stability, and adherence of protective scales.

Silica layers may also serve as protective scales, but Fe – Si alloys are not used as high-temperature materials. Formation of Fe_2SiO_4 and an inner layer of SiO_2 plays a role in the annealing of silicon sheet for electrical applications.

6.1.2.2.13. Effects of Chlorine in Oxidation

The presence of chlorine may cause acceleration of oxidation, so-called "active oxidation" [472–475]. Especially in waste PVC and NaCl-containing coal incineration, HCl and chlorides from combustion react with the oxide scale on steels to form chlorine

$$82\,HCl + {}^1/_2\,O_2 \longrightarrow H_2O + Cl_2 \qquad (6.19)$$

$$2\,NaCl + Fe_2O_3 + {}^1/_2\,O_2 \longrightarrow Na_2Fe_2O_4 + Cl_2 \qquad (6.20)$$

The chlorine penetrates the scale and reacts at the oxide – metal interface to form $FeCl_2$ which evaporates and oxidizes according to

$$2\,FeCl_2(g) + {}^3/_2\,O_2 \longrightarrow Fe_2O_3 + 4\,Cl_2 \qquad (6.21)$$

The chlorine partially diffuses inward and reacts again, thus establishing a circuit, in which Cl_2

catalyzes the "active corrosion" (active, since no dense oxide layer passivates the steel). This process causes problems in waste incineration and other processes in oxidizing, chloridizing atmospheres. Not only are low-alloy steels strongly attacked, but also chromia-forming high-alloy steels, due to the reaction

$$4\,NaCl + Cr_2O_3 + {}^5/_2\,O_2 \longrightarrow 2\,Na_2CrO_4 + 2\,Cl_2 \qquad (6.22)$$

The chlorine produced penetrates the scale and causes formation of volatile chlorides of the alloy components.

6.1.2.2.14. Sulfidation of Iron and Steel

The main sulfidation products of iron in sulfidizing environments are pyrrhotite FeS and pyrite FeS_2. Pyrrhotite, like FeO, is highly nonstoichiometric, owing to cation vacancies, their concentration being dependent on sulfur partial pressure and temperature [476], [477]. Accordingly, the diffusivity of Fe in FeS is high and the FeS growth rate is very rapid, even at relatively low temperature. As in the case of FeO, the linear rate law (Equation 6.15) applies for growth in $H_2S - H_2$ atmospheres [478], [479]; k_1 depends on $p(H_2S)$ and is inversely proportional to the sulfur activity on the sulfide surface. The rate- controlling step is transfer of S_{ad} from H_2S to the surface, which is retarded with increasing sulfur activity. Upon sulfidation, rate control gradually changes to solid-state diffusion and to the parabolic rate law [480]. Corrosion by H_2S is a problem in the petrochemical and chemical industries, and is not easily suppressed. Even steels with Cr content up to 17 % do not behave much better than low-alloy steels [481].

During corrosion of iron in SO_2 or $Ar - SO_2$ mixtures at 600 – 1000 °C, the phases FeO and FeS grow simultaneously on the metal surface [482–484], if the transport in the gas phase or the phase boundary reaction is rate determining. Owing to the high diffusivities of cations in FeS, lamellae of FeO and FeS grow side by side up to a layer thickness of ca. 150 µm, following a linear law. In the application of steels in flue gases, a scale of Fe_2O_3/Fe_3O_4 is stable on the steel surfaces and SO_2 should have no effect on oxidation. However, if SO_2 penetrates the scale, at the interface sulfides can be formed. The mass action law for the reaction $SO_2 = {}^1/^2\,S_2 + O_2$ predicts that very high sulfur pressures are possible at the oxide – metal interface, since $p(O_2)$ is very low there. This is especially dangerous in high-Ni alloys, since $Ni - Ni_3S_2$ forms a liquid eutectic at 645 °C, and the presence of such melts strongly aggravates corrosion.

Sulfidation of heat exchangers is a problem in coal gasifiers; chromia-forming steels have been tested at 700 – 800 °C [485–489] but fail after lifetimes of some hundreds or thousands of hours. Preoxidation has been used to improve protection, but the chromia layers generated can also fail after similar lifetimes, either by external sulfidation, i.e., growth of sulfides of Fe, Ni, and Mn on the chromia scale, or by internal sulfidation, formation of sulfides of Cr and Mn beneath the scale.

6.1.2.2.15. Carburization

Carburization in gas atmospheres is a technical process for case hardening of steels, a specified carbon content is established in the surface, and the carburized components are quenched in oil for hardening [490], [491]. Carburization can also be an unwanted process in the high-temperature corrosion of materials, e.g., cracking tubes in petrochemistry, and heating tubes or grates in industrial furnaces. In this process, carbon diffuses into the alloy and carbides are precipitated, mainly chromium carbides M_7C_3 and $M_{23}C_6$, with loss of both ductility and oxidation resistance [492], [493].

In both cases, the carbon transfer is by reactions in which CO, CH_4 or hydrocarbons decompose on the metal surface [494], [495], the transfer is very fast by the reaction:

$$CO + H_2 \longrightarrow C + H_2O \qquad (6.23)$$

less fast by:

$$2\,CO \longrightarrow C + CO_2 \qquad (6.24)$$

and very slow by:

$$CH_4 \longrightarrow C + 2\,H_2 \qquad (6.25)$$

Rate equations and rate constants for these reactions have been determined for iron and binary iron alloys. The reactions are strongly retarded by sulfur [496].

In gas carburization for case hardening, the process is jointly controlled by the phase boundary reaction and inward diffusion of carbon; this has been studied in detail, and can be controlled well, to obtain certain penetration profiles of carbon in different steels and corresponding hardness profiles [497].

The unwanted carburization of cracking tubes [492], [493], [498] is generally suppressed, or at least retarded, by the oxide layer on the high-Cr – Ni steels used, only small amounts of carbon are transferred through pores or cracks formed on creep of the tubes. However, failure occurs if the tubes are heated above 1050 °C; the coke in the tubes reacts with Cr_2O_3 to chromium carbides which are no longer protective, and relatively fast carburization takes place [493]. This may happen during decoking of the tubes in $H_2O - H_2$ mixtures, when the temperature is not sufficiently controlled. Under these conditions, materials with 1 – 2 % Si are resistant because of the protective effect of an inner SiO_2 layer beneath the chromia layer. Small amounts of sulfur in the atmosphere can also retard carburization.

Metal dusting [499–503] is the disintegration of steels into a dust of metal particles and carbon, occurring in atmospheres of $a_C > 1$ (carbon activity $a_C = 1$ means equilibrium with graphite) and in recent years has become problematic. The reaction sequence: (1) supersaturation of the metal with dissolved C; (2) formation of metastable carbide at $a_C > 1$; (3) deposition of graphite on this carbide ($a_C \to 1$); (4) decomposition of the carbide to carbon and metal particles; and (5) deposition of further graphite from the atmosphere on the metal particles. This leads to metal wastage and the formation of the loose corrosion product "coke," which is easily removed by fast gas flow in the plants, leaving pits and holes. Protection is possible by the chromia layer on high-alloy steels – their resistance depends on their ability to form oxide layers and healing. Furthermore, sulfur can protect since adsorbed sulfur effectively poisons steps (1), (3), and (5) of the reaction sequence, however, addition of sulfur is not possible with synthesis gas ($CO + H_2$) for the production of methanol, hydrocarbons, etc.

6.1.2.2.16. Nitriding

Similar to carburization, there is a technical process of nitriding for surface hardening, and an unwanted corrosion process at high temperatures which leads to nitride formation in steels and losses in ductility and oxidation resistance.

The nitrogen transfer can be from N_2, $NH_3 - H_2$ mixtures, or by plasma nitriding in a glow discharge. The latter process is performed since N_2 is rather inert; nitrogen transfer:

$$N_2 \longrightarrow 2\,N\ (\text{dissolved}) \tag{6.26}$$

is slow, with high activation energy [504]. Much faster is:

$$NH_3 \longrightarrow N\ (\text{dissolved}) + {}^3/_2\,H_2 \tag{6.27}$$

So $NH_3 - H_2$ mixtures can be used for nitriding and nitrocarburizing (with CO) at relatively low temperature. Their nitrogen partial pressures are [504] very high as calculated from the mass action law; the equilibrium values are of the order of 10^5 kPa N_2. This may lead to deterioration of the nitrided case, by void formation with condensation of dissolved N at lattice defects to molecular N_2, which can develop high pressure, corresponding to the N_2 partial pressure of the $NH_3 - H_2$ mixture, and form small bubbles in the material.

Nitriding for surface hardening leads to a layer of ε-nitride on the steels.

Nitriding of high-alloy steels happens only at high temperature > 1000 °C, e.g., on burner tubes [505], [506] and after failure of the oxide scale by cracking or spalling; mainly chromium nitrides Cr_2N are formed in the metal matrix.

6.1.2.2.17. Decarburization, Denitriding, and Hydrogen Attack

Thorough decarburization of steel is necessary for several applications, e.g., sheet for single-layer enameling, deep drawing steels, and silicon steels for use in generators and transformers. Decarburization is performed at 700 – 900 °C in wet hydrogen, and is controlled by carbon diffusion to the surface. The product $c_c D_c$ (solubility × diffusivity) is critical, and has a maximum at ca. 800 °C [507], [508]. The surface reactions are the formation of CO and CH_4, i.e., the back reactions of Equations (6.23) and (6.25), CH_4 formation being negligible.

Denitrogenation [509], [510] is also important for deep drawing and electric sheet, this is also conducted in wet H_2 at ca. 750 °C, and occurs by NH_3 formation and N_2 desorption, the back reactions of Equations (6.22) and (6.23). The presence of some H_2O accelerates the rate of NH_3 formation [511], [512], but electric sheet with Si cannot be denitrogenated in wet hydrogen since SiO_2 formation retards the process.

In processes which involve high hydrogen partial pressures at elevated temperatures (hydrogenation reactions, ammonia synthesis), considerable amounts of atomic hydrogen enter the walls of steel vessels, and the cementite in unalloyed steels is attacked and methane is formed. Dissolution of the Fe_3C and precipitation of CH_4 and H_2 at interfaces and defects in the steel cause weakening and embrittlement of carbon steels. The more stable carbides in low-alloy Cr and Cr – Mo steels are resistant to hydrogen attack in the usual temperature range for the processes in question; the stability ranges of different steels as functions of temperature and hydrogen partial pressure are compiled in Nelson diagrams [513].

6.1.2.3. Physical Properties

Knowledge of the physical properties of steel is important for controlling its structure, and hence its properties. In this Section, the physical properties of pure iron are described first, followed by those of the solid solutions of the various iron modifications, and finally some other factors that influence structure [514].

6.1.2.3.1. Pure Iron

Crystal Structure. Iron occurs both in body-centered cubic (bcc) and face-centered cubic (fcc) structures. The bcc α-phase, which is stable at lower temperatures, is ferromagnetic up to the Curie temperature $T_c = 1041$ K, and is transformed into the paramagnetic state at higher temperatures (above the A_2 point). At 1184 K, the A_3 point, α-iron is tranformed into the fcc form, γ-iron. The stability range extends up to 1665 K (A_4 point). Between 1665 and 1807 K, iron has a bcc structure, again δ-iron. Pure iron melts at 1807 K.

The crystal structures of α- and γ-iron are shown in Figure 267. The number of atoms in the unit cell is 2 in the bcc structure and 4 in the fcc structure. The number of nearest neighbors is 8 and 12 respectively, and of next nearest neighbors 6. The lattice constant of α-iron at room temperature $a_{RT} = 0.28662$ nm. Thermal expansion data are shown in Figures 268 and 269. In Figure 268, the difference in the y-axis scales for the bcc and fcc structures is due to the difference in the number of atoms per unit cell. The calculated density is $\varrho = 7.876$ g/cm^3.

Figure 267. Crystal structure of α- and γ-iron

Figure 268. Effect of temperature on the lattice constant of iron

Figure 269. Effect of temperature on the atomic volume of iron

The coefficient of linear thermal expansion α (Fig. 270) increases with increasing temperature, and is higher for the fcc than for the bcc phase. The hatched area between the measured and calculated curves is due to a magnetostrictive effect in the region of the Curie temperature.

Figure 270. Effect of temperature on the thermal expansion coefficient of iron

Specific Heat Capacity. The specific heat capacity of a substance is the heat required to increase the temperature of unit mass by 1 K. The effect of temperature on its value is of fundamental importance, as the specific heat capacity is used in the calculation of enthalpy and entropy. The results of some determinations are plotted in Figure 271, with the most probable values indicated by a continuous curve [515]. The broken curves refer to the region of instability of the bcc and fcc phases.

The heat capacity is the sum of various components. There is a sharply defined maximum in bcc iron in the region of the Curie temperature. This represents the magnetic component, due to the energy required to destroy the magnetic ordering that occurs during the ferromagnetic – paramagnetic transition.

Elastic Properties. The modulus of elasticity (Young's modulus E) represents the relationship between the elastic extension or strain and an applied tension or stress σ. This obeys Hooke's law $\sigma = E\varepsilon$. The effect of temperature on E is illustrated in Figure 272 (the values were determined for polycrystalline iron). In single crystals, the modulus of elasticity is strongly dependent on the crystallographic orientation of the sample (anisotropy). This anisotropy is also apparent in materials with a well-defined texture.

Figure 272. Moduli of elasticity and compressibility of iron [520]

Figure 271. Effect of temperature on the molar heat capacity of iron
Solid line, most probable values; dashed line, values calculated for the instability ranges of α- and γ-iron
• According to [516]; △ According to [517]; △ According to [518]; ○ According to [519]

Volume changes under hydrostatic pressure are described by the compressibility κ, shown as a function of temperature in Figure 272.

Magnetic Properties. Individual iron atoms have a permanent magnetic moment. At temperatures above the Curie temperature, the directions of the magnetic moments are randomly distributed, and the material is paramagnetic. There is a linear relationship between field strength and polarization, represented by the volume susceptibility.

Below the Curie temperature, the magnetic moments of neighboring atoms in the bcc lattice are arranged parallel to each other, and the iron is ferromagnetic. Within the Weiss zones (magnetic domains) the moments are all in the same direction. This direction may differ from the direction within neighboring domains, so that they cancel each other.

Figure 273. Magnetization curve of a ferromagnetic material
H = field strength; J = polarization ($B = J + \mu_0 H$ = induction); J_s = saturation polarization; J_r = remanence; H_c = coercive field strength; $\oint H dJ$, the area of the hysteresis loop, gives the amount of energy liberated as heat on reversal of the direction of magnetization. This is the hysteresis loss, quoted per unit mass

The properties of a ferromagnetic material can be represented by the magnetization curve (Fig. 273). With increasing field strength H, the polarization increases as the number of favorably oriented magnetic domains increases, and the magnetic moments align in the direction of the applied field. The maximum value is the saturation polarization. If the applied field is removed, the residual polarization at $H = 0$ is the remanence. The coercive field strength is the applied field which reduces the polarization to zero.

The saturation polarization varies with temperature, and disappears at the Curie temperature [521], [522]. The magnetization curve for single crystals varies with crystal orientation, being steepest in the [100] direction, and considerably less steep in the [111] direction. This effect is utilized in the manufacture of textured electroplated steel.

Electrical Properties. The high electrical conductivity of iron is due to the great mobility of the free electrons, but their movement is scattered by deviations from the periodic lattice potential or by the electrons of unfilled shells. All crystal defects, e.g., holes, dislocations, stacking faults, impurity atoms, and precipitates, lead to energy losses by the motion of free electrons, and hence to an electrical resistance that falls to the so-called residual resistance at absolute zero. According to the Matthiessen rule, resistance is made up of a temperature-dependent part, due to lattice vibrations, and a residual resistance which is independent of temperature. The effects of the magnetic and the $\alpha - \gamma$ transitions can also be seen in Figure 274.

Figure 274. Effect of temperature on the electrical resistivity of pure iron

At high temperatures, thermal conductivity is a result of the same processes that lead to electrical conductivity. The thermal conductivity – temperature curve is similarly affected by the magnetic transformation as shown in Figure 275 [515], [523]. According to the Wiedemann – Franz – Lorenz law, the ratio of

thermal conductivity to electrical conductivity is directly proportional to temperature. From this relationship, thermal conductivity can be calculated from electrical conductivity even at high temperatures when direct determination is difficult.

Figure 275. Effect of temperature on the thermal conductivity of pure iron

Figure 276. Effect of alloying elements on the lattice constant of α-iron

6.1.2.3.2. α-Iron Solid Solutions

As described in Section 6.2.1, alloying elements can be divided into those that restrict the γ-region, and those that stabilize the γ-phase and extend its limits [524]. The effect of alloying additives on the transformation behavior of steel can be understood only from knowledge of the effect on various properties. Almost all alloying elements cause a volume increase. Figure 276 shows their effect on the lattice constant of α-iron. Only silicon leads to a contraction. Electrical resistance increases in proportion to the concentration of the alloying element (Fig. 277). The most significant effect of alloying elements on magnetic properties is on the Curie temperature, as this affects the temperature of the transformation from γ- to α-iron. Figure 278 shows the effects of various elements. The large increase caused by cobalt is of special interest.

Figure 277. Increase in the electrical resistivity of α-iron by alloying elements

Figure 278. Effect of alloying elements on the Curie temperature of α-iron

The temperature dependence of the physical properties of α-iron mixed crystals is closely linked to their magnetic behavior, and is not significantly different from that of pure iron. For example, the heat capacity of iron – chromium

alloys is essentially constant if the temperature scale is based on the Curie temperature.

Ferritic iron – silicon alloys are of special importance, as these have low magnetization losses [521], [525]. Silicon addition increases electrical resistance, and hence reduces eddy current losses. The crystal anisotropy energies and the consequent hysteresis losses are reduced. Addition of $> 4.5\,\%$ Si prevents the $\alpha - \gamma$ transformation, and enables a coarse grain structure to be produced. Texturing allows the magnetic anisotropy to be exploited.

6.1.2.3.3. γ-Iron Solid Solutions

The magnetic properties of austenitic iron alloys are complex – as ferromagnetism, antiferromagnetism, and paramagnetism can occur. Iron – manganese [526], iron – nickel [527], and iron – nickel – manganese alloys [528] are of industrial importance.

The thermal expansion coefficients of paramagnetic γ-alloys (e.g., iron – manganese – nickel and iron – nickel – chromium alloys) are relatively high at room temperature. This is utilized in bimetallic systems [529]. Conversely, a large volume magnetostriction in magnetically ordered alloys compensates for thermally induced changes to the lattice dimensions; only a small amount of thermal expansion takes place over a certain temperature range [530]. Iron alloys containing 35 % nickel are examples of Invar alloys of this type.

6.1.2.3.4. Other Effects of Structure

In general, physical properties are influenced by lattice defects. Density is somewhat decreased by lattice defects. All lattice defects increase the residual electrical resistance, whereas lattice vibrations are the main cause of resistance at high temperatures. Spontaneous magnetization and the Curie temperature depend mainly on lattice structure and composition. However, the magnetization curve is strongly influenced by the structure; lattice defects tend to prevent movement of the domain walls, and hence increase the remanence and coercive field strength.

In multiphase structures, the different properties of the phases must also be considered. These properties combine in proportion to the volume ratios in only the simplest cases, e.g., density, heat capacity, heat of transformation, and heat of formation, provided that the phases are in a coarse state of subdivision. A systematic treatment is not yet possible. Probably the most important industrial application is represented by the "hard" or permanent magnetic materials, with high coercive field strengths and a high *BH* value.

6.1.3. Heat Treatment

6.1.3.1. Time – Temperature Transformation Diagrams

Under technical conditions, desired microstructures can be produced by isothermal transformation or continuous cooling. In practice, temperature – time treatments intermediate between these extremes are used, and the steel is sometimes also mechanically formed during cooling. The progress of such transformations is shown in time – temperature transformation (TTT) diagrams (see Figs. 191 and 192). By special measuring techniques, the effect of deformation on the transformation behavior can be measured and represented in TTT diagrams. A general representation of transformation behavior is possible only by computer simulation of the transformations of the microstructure [256], [531], [532]. The following treatment is mainly restricted to the continuous cooling process (Fig. 192).

The addition of alloying elements enables the M_S temperature and the time required for a transformation in the pearlite and bainite ranges to be shifted within wide limits [277], [278], [280]. Figures 279 and 280 show continuous cooling transformation (CCT) diagrams for a hypoeutectoid alloy steel and a tool steel [299]. With Ck 45 steel (see Fig. 192), 45 vol % ferrite and 55 vol % pearlite are formed during a cooling period of 300 s to 500 °C. When this cooling process is applied to the tool steel shown in Figure 280, it produces 100 % martensite, apart from the proeutectoid carbide precipitation (K). Therefore, another method of influencing the microstructure of a workpiece, apart from the temperature – time treatment, is by choice of its chemical composition. However, steels with the

Figure 279. CCT diagram for continuous cooling of 50 CrMo 4 steel [299]
A) Temperature – time curve in the surface zone (R) and the core (K) of cylinders of various diameters for oil cooling. The surface zone extends below the surface by 10 % of the diameter; B) 0.2 % offset yield stress $R_{p0.2}$, tensile strength R_m, elongation at fracture A, and reduction in area at fracture Z for test pieces with the given durations of cooling to 500 °C

lowest possible alloy content are used in any given application, for reasons of cost [533].

6.1.3.2. Heat Treatment of Transformable Steels

6.1.3.2.1. Austenitizing

With transformable steels, the first step in many heat treatments is austenitizing. In an industrial situation, the austenitizing temperature selected for hypoeutectoid steels is 30 – 50 °C above Ac_3 (see Fig. 188), and, for hypereutectoid steels, 30 – 50 °C above Ac_1 [534–536]. These temperatures are given in the relevant standards [537], [538]. The annealing times required for the formation of a homogeneous austenite can be found from the time-temperature austenitization (TTA) diagrams [274], [275], e.g., Figure 190. The tool steels are an exception to this, and the temperatures needed to dissolve the special carbides are given in the relevant standards. These temperatures lie in the two-phase austenite + carbide region ($\gamma + M_3C$ in Fig. 188, A + K in Fig. 280). As well as M_3C, other carbides occur in these steels, e.g., M_7C_3, $M_{23}C_6$, M_2C, or MC. If these carbides remain undissolved during austenitizing, they improve wear resistance [289], [290].

The industrial austenitizing of heat treated engineering steels leads usually to the formation of a homogeneous austenite with small grain size (see Fig. 190). If low austenitizing temperatures and short times are used, the austenitization is dependent on the initial state. Thus, although a

Figure 280. CCT diagram for X 38 CrMoV 51 tool steel [277].
Austenitization at 1030 °C for 15 min; RA residual austenite
In circles, the hardness at room temperature is given for each cooling curve.

microstructure produced by quenching and tempering leads to a rapid and uniform distribution of the carbon, if the starting condition is a ferritic – pearlitic microstructure corresponding to Figure 194, the carbides in the pearlitic region must first dissolve, and this carbon, now in the austenite, diffuses into the zones that consisted of low- carbon ferrite in the initial state. This requires extra annealing times, or an increase in temperature for the same annealing time, in order to obtain a homogeneous austenite. When using TTA diagrams to plan an isothermal temperature – time process, the austenitization time should start after the workpiece has been heated throughout.

6.1.3.2.2. Transformations

As industrial cooling operations are usually carried out continuously in air or liquid media, the temperature – time curve at the center and near the surface of the workpiece is different, and depends very much on the dimensions (Fig. 279) [539], [540]. The following discussion applies only to dimensions for which the stated cooling regimes are feasible (see Section 6.1.3.2.3).

Transformation in the Pearlite Range. A transformation in the lower region of the pearlite range is used in wire patenting [541]. This forms pearlite with very small interlamellar distances which has very good wire-drawing properties. As the diameter is small, the transformation can be carried out isothermally. Other applications include the production of rails, in which pearlite is formed at low temperature using the heat of the rolling [542]. In plain carbon steels, a ferritic – pearlitic microstructure can be produced by air cooling (Fig. 192). A corresponding heat treatment is known as normalization [534–536], [538], [541]. Delayed cooling is necessary with alloy steels, especially in thin sections, if a ferritic – pearlitic microstructure is desired (Fig. 279 and 280).

Transformations in the Bainite Range. In bainitization, a microstructure consisting only of bainite is produced in an isothermal transformation (Fig. 191). Whereas continuous cool-

ing cannot in principle give a 100 % bainite microstructure (see Fig. 279), microstructures formed in the upper temperature region of the bainite range have a much coarser microstructure than those formed in the lower region of the pearlite range (see Fig. 200). These coarsely bainitic microstructures usually have poor toughness properties for their yield strengths. On the other hand, microstructures formed in the lower region of the bainite range (see Fig. 199) have very favorable combinations of toughness and yield strength, often matching the properties of annealed martensite [288], [293], [541].

Transformations in the Martensite Range. Martensite can be obtained by cooling so rapidly that the formation of microstructures of the pearlite and bainite range is suppressed. For 50 CrMo 4 steel this requires a cooling time to 500 °C of ≤ 20 s (Fig. 279). Plain carbon steels must usually be water-quenched to achieve this. As martensite is the hardest of all the steel microstructures, the process of martensite formation is known as hardening [534], [535], [541]. The effect of the cross section of the workpiece is discussed in Section 6.1.3.2.3. Owing to the high rates of cooling, large temperature differences between the outer and inner regions of the workpiece occur (see Fig. 279), so that stresses and residual stresses are produced that can lead to cracking. These hardening cracks impose a limit to heat treatment processes involving rapid cooling of large or complex workpieces [543], [544].

With alloy steels, e.g., tool steels which need long time for transformation (Fig. 280), martensite can be produced by air cooling in components with small cross sections made of transformable steel, so that the limitations due to interior stresses are mostly avoided [289], [541]. Hardened steels are annealed at 100 – 150 °C, as the yield strength is hardly altered up to these temperatures, and the toughness can be considerably improved [289].

6.1.3.2.3. Effect of Dimensions

Figure 279 shows the temperature – time curves for the outer and inner zones of cylinders of various diameters. The temperature differences between these zones can be very great, especially with cooling media that cool rapidly, and this leads to the formation of different microstructures in the outer and inner zones [539], [545]. This must be borne in mind when deciding on the heat treatment process needed to give particular properties. An increase in the cooling period $t_{8/5}$ decreases the yield strength $R_{p0.2}$ and increases the elongation at fracture A and reduction in area at fracture Z (Fig. 279) [539]. Figure 281 shows how the hardness varies over the cross section of cylinders of different steels; for an oil-quenched plain carbon steel Ck 45, maximum hardness (see Fig. 197) is not reached, even near the surface. Maximum hardness can be obtained over only ca. 40 % of the section with 50 CrMo 4 steel; a purely martensitic microstructure is produced near the outer surface.

Figure 281. Hardness variations over the cross section of cylinders of diameter 40 mm fabricated from various steels after quenching in oil [299]

6.1.3.2.4. Quenching and Tempering

Quenching and tempering consists of hardening followed by annealing. As stated in Section 6.1.1.4, the tempering of martensite can give

any yield strength between that of martensite and that of a soft-annealed microstructure. The relationship between tempering temperature and yield strength is known for many grades of steel (Fig. 282) [536], [538]. Because the arrangement of carbides in the ferrite is very uniform and homogeneous after martensite is tempered, this process gives very good toughness properties for a given yield strength, considerably better than ferritic – pearlitic microstructures or microstructures produced in the upper temperature region of the bainite range [288], [293].

Figure 282. Variations in mechanical properties as a function of the tempering temperature of 50 CrMo 4 steel [538]

6.1.3.2.5. Spheroidized Annealing

Figures 279 and 280 show that, in high alloy steel components of small dimensions, microstructures of appreciable hardness can be produced, even with air cooling, and these can give machining problems. The carbides are often spheroidized by means of a prolonged annealing process at temperatures just below Ac_1 [546], i.e., coarse carbides are formed in the ferrite (Fig. 283). This process, spheroidize annealing, can be accelerated by an oscillation around A_1, or by a prior deformation process [536], [541], [547].

Figure 283. Microstructure after spheroidize annealing of C 130 steel
Carbides (gray – black) in ferrite (white); fine lines are ferrite grain boundaries; 810 °C for 15 min (water), and 720 °C for 8 h (air); ×500, etched with sodium picrate + nital

6.1.3.2.6. Thermomechanical Treatment

In Section 6.1.2, it was shown that high yield strengths and good toughness properties can be ensured only if the carbides are fine and homogeneously distributed. A fine-grained austenite can be produced at low austenitizing temperatures and with short annealing times, even though this leads to incomplete dissolution of the carbides (Fig. 190). As only part of the carbon in the austenite is dissolved, there is a reduction in the maximum hardness (Fig. 197). With engineering steels, which are not heat treated by the user, a very fine grain can be produced during manufacture by a hot deformation process in the austenite region, followed by recrystallization [548–552]. An example of the effect of the initial grain size and the deformation temperature is shown in Figure 284 [553]. If a fine-grained austenite of this type is cooled in a controlled manner, the very fine-grained transformation microstructures ferrite – pearlite, bainite, or even martensite are formed, depending on the cooling rate and chemical composition of the steel [554].

Another method of obtaining a very fine microstructure is to add suitable elements, e.g., Nb or Ti, to prevent recrystallization after deformation of the austenite at low temperature, and

Figure 284. Static recrystallization of a steel with 0.038 % C, 1.8 % Mn, 0.28 % Mo, 0.07 % Nb, and 0.009 % N for two initial grain sizes
Deformed by one pass; $\varphi = \ln (d_0/d)$, d_0 = starting thickness, d = final thickness [553]

to allow the transformation from the uncrystallized austenite to take place [555]. This requires very precise control of the temperature – time curve, especially at the end of a rolling operation [553], [556]. The transformation of an unrecrystallized austenite proceeds more quickly than that of a recrystallized austenite [557]. The two processes can be combined. At temperatures at which rapid recrystallization of austenite takes place, e.g., slightly above Ac_3, hot deformation produces a fine austenite grain. This fine austenite is subsequently deformed at lower temperatures (e.g., at or below Ac_3) such that recrystallization of the austenite is avoided. It is then immediately cooled and the transformation initiated. The temperature – time curve and the degree of deformation must be correct for the steels concerned, and the chemical compositions of the steels must be suitable for the available plant equipment. Transformations in the pearlite, bainite, or martensite range are carried out according to the desired application properties. Elements such as Nb and Ti which are added to delay recrystallization can give precipitation hardening during the cooling [558–561].

6.1.3.2.7. Surface Hardening

For technical applications, it is often desired that the surface of a workpiece should be hard in order to provide wear resistance. However, as the load-bearing forces are comparatively small, the total section can have a low yield strength. In this case, it is reasonable to heat treat the workpiece at the surface only, giving high yield strength, while leaving the interior ductile and tough. Because of the treatment necessary, residual compressive stresses are usually produced at the surface, and this also improves fatigue resistance. Because of the internal stresses, the properties of the workpiece can no longer be described by the properties of the material only.

There are two fundamental methods of hardening the surface zone [541]:

1) Hardening by heat treatment, using a temperature – time regime derived from the transformation characteristic
2) Modification of the chemical composition in the surface zone

As shown in Figures 279 and 281, oil quenching of a workpiece, diameter 40 mm, consisting of 50 CrMo 4 steel, produces only small differences in hardness between the surface and the interior. If only the surface zone of a workpiece is austenitized and quenched, the interior temperature does not exceed Ac_1. The interior is very highly tempered, and further cooling has no further effect on its strength. Only the austenitized surface zone is hardened, so that, on tempering, a hardened and tempered high-strength surface zone is produced, surrounding a comparatively ductile core. The depth of hardening can be influenced by the temperature – time regime selected. A process used for this type of surface hardening is induction hardening [541].

In case hardening, steel is placed in a carbon-containing medium at ca. 950 °C, and carbon diffuses into the surface zone [534–536], [562], [563]. The most common technique is gas carburization, which is very easy to control. The carbon which is taken up (see Fig. 197) increases the hardness after quenching, but transformation of the austenite is delayed. However, by using an appropriate cooling medium for the dimensions of the workpiece, the two effects can be used to give the maximum hardness and depth of hardening. Surface hardening in very thin layers can be produced by nitriding, chromizing, and boronizing [534], [535], [541], [564].

6.1.3.3. Heat Treatment Without Transformation

With nontransformable austenitic or ferritic steels, the only aims of the heat treatments are to cause recrystallization to give a desired grain size, to quench a steel that has been heated to dissolve precipitated phases, and sometimes to temper after precipitation hardening. Strictly speaking, the annealing stage of the tempering process (see Section 6.1.3.2.4) is a heat treatment without transformation. However, the most important heat treatment of this type is recrystallization.

6.1.3.3.1. Recrystallization

Mechanical deformation of steel causes gliding which leads to a large increase in dislocation density, and hence to a high level of stored energy [565], [566], (see Section 6.1.2). Dislocations of opposite sign attract one another. If the temperature is high enough to permit easy movement of the dislocations, defects of opposite sign migrate and annihilate each other. The dislocation density and stored energy decrease. This process is known as recovery. Recovery proceeds more quickly at higher temperatures and for higher stored energies. In steels at 400 °C it takes place in hours, and >700 °C in seconds, although these times can vary by a factor of ten, depending on the chemical composition of the steel. If the recovery process, e.g., at 600 °C, rapidly forms small local regions with very low dislocation densities, these regions, which have high-angle grain boundaries, grow into the neighboring regions (recrystallization). The lower the degree of mechanical deformation, the higher is the temperature that leads to a measurable recrystallization rate, and the larger are the grains produced by the recrystallization (Fig. 284) [567].

For steels above 900 °C, in the austenitic region, recrystallization is often so rapid that it can take place during a deformation process. This is referred to as dynamic recrystallization, in contrast to static recrystallization (which only occurs after deformation ceases). At the end of the primary recrystallization described above, the high dislocation densities produced by the deformation in all the grains are just removed. In secondary recrystallization, grain growth proceeds further (Fig. 190), as the single crystal is the thermodynamically stable state, and large grains grow at the expense of small grains. The addition of alloying elements, e.g., Nb and Ti, can cause recrystallization in the austenite region to be slowed down so much that, after the deformation caused by rolling, the steel can be transformed without recrystallization. This is utilized in thermomechanical treatment (see Section 6.1.3.2.6). Figure 284 shows the fundamental influence of the starting size of the grains, deformation temperature, and degree of deformation, provided that the effect of Nb carbonitride precipitation, which has not been extensively researched, is not superimposed.

In the deformation of steels in the α-iron region, preferred orientations are produced. This is caused by the gliding processes that occur [565]. In accordance with the recrystallization sequence outlined above, recrystallization starts in grains with the highest energy density, and a certain orientation relative to the frame of reference during deformation, e.g., to a steel sheet. On recrystallization, grains of one particular orientation begin to grow sooner than others, which leads to a higher concentration of grains of this orientation at the end of the primary crystallization than would be expected for a random distribution. The textures so produced are used in the production of deep-drawing sheets to give favorable deformation properties of the steel. With electric sheets, these textures enable the magnetic anisotropy of the body- centered cubic lattice to impart improved electrical properties [270], [568].

6.1.3.4. Simulation of Heat Treatment

For transformable steels, there are limitless possibilities for transforming austenite in the pearlite, bainite, or martensite range, using controlled temperature – time regimes. Finding an optimum temperature – time regime to produce a desired microstructure, and hence the specified properties, requires a very large number of experiments. Models representing transformation behavior have been developed which can be used to calculate the progress of transformations [531], [569], [570]. Similarly, knowing the temperature and degree of deformation, grain sizes of the austenite after heat treatment of particular grades of steel can be calculated, so that the transformations that take place during fabrication can be simulated [571], [572]. If the mechanical properties of the individual microstructures of a steel are known, the final properties produced by a given process can also be calculated [573]. In this way, a proposed process can be simulated in advance. Also, deviations at the start of the process sequence can be rectified by changes at its end.

6.2. Uses

6.2.1. Classification of Steel and Steel Products

6.2.1.1. General

The existence of so many grades of steel and steel products makes it essential to have an agreed terminology to facilitate communication between producers, users, and traders in these materials. This is necessary not only within the European Common Market, but also for world trade. In the early 1990s, ca. 30 % of steel products were exported from the countries producing them (Table 22).

Table 22. World steel exports by product 1992 ∗

Product	Exports, $\times 10^6$ t
Ingots and semifinished material	12.9
Railway track material	0.9
Concrete reinforcing bars	5.5
Hot-rolled bars and rods	4.3
Angles, shapes and sections	10.2
Wire rod	8.0
Hot-rolled strip	1.9
Plates	9.4
Hot-rolled sheets and coils	22.4
Cold-rollled sheets and coils	17.1
Galvanized sheet	9.6
Tinplate and blackplate	4.6
Other coated sheet	3.9
Wheels (forged and rolled) and axles	0.1
Steel tubes and fittings	14.0
Drawn wire	2.1
Cold-rolled strip	1.4
Cold-finished bars and rods	1.3
Castings	0.1
Forgings	0.6
Total	130.4

∗ International Iron and Steel Institute: World Steel in Figures, 1994.

The International Standards Organization (ISO) and the European Committee for Iron and Steel Standards (ECISS) have issued standards over many years, including definitions of steel products (EN 10 079) and a system for classifying grades of steel (EN 10 020).

Designation systems for steels have been agreed in Europe (EN 10 027-1, -2), but are not yet thoroughly established.

6.2.1.2. Definitions for the Classification of Grades of Steel

Steel is a general term for materials in which the iron content is higher than that of any other element, and in which the carbon content is normally $< 2\,\%$.

According to EN 10 020, steel is divided into unalloyed and alloyed grades, according to its chemical composition, and these grades are further subdivided into principal quality groups, based on their most important properties and uses. The starting point is the minimum level of each element in the melt, specified in the standard or in the terms of delivery. The harmonized system for customs nomenclature is based on other physical quantities.

Unalloyed steels are those in which the level of an individual element in no case reaches or exceeds the limiting concentration given in Table 23.

Table 23. Concentration limits of elements for classification as base or alloy steel

	Element	Limiting concentration, %
Al	Aluminum	0.10
B	Boron	0.0008
Bi	Bismuth	0.10
Co	Cobalt	0.10
Cr	Chromium *	0.30
Cu	Copper *	0.40
La	Lanthanides (assessed separately)	0.05
Mn	Manganese	1.65 ***
Mo	Molybdenum *	0.08
Nb	Niobium**	0.06
Ni	Nickel *	0.30
Pb	Lead	0.40
Se	Selenium	0.10
Si	Silicon	0.50
Te	Tellurium	0.10
Ti	Titanium **	0.05
V	Vanadium **	0.10
W	Tungsten	0.10
Zr	Zirconium **	0.05
Others (except C, N, O, S), each		0.05

* If two, three, or four of these elements are present in concentrations less than the maxima permitted, their total concentration must not exceed 70 % of the sum of the maxima. ** The same rule applies to these elements. *** If the manganese content is quoted as a minimum, this value applies.

In an alloy steel, the content of an individual element reaches or exceeds the limiting values quoted in Table 23 in at least one case.

From general economic considerations, special regulations have been set for some product groups, e.g., weldable fine-grained structural steels, free-cutting steels, electric sheets, and rails. Only the fundamental principles of this system are described here.

Other terms are often used, e.g., microalloyed steels, which contain small additions of, e.g., Nb, V, or Ti, usually in association with a thermomechanical treatment of the steel product. Other common expressions are lowalloy steel, which contains $< 5\,\%$ alloying elements, and HSLA (high-strength, low-alloy) steel.

EN 10 020 further divides steels into the following main quality groups:

Base steels are those whose quality specifications do not require special processing during manufacture. They are generally unsuitable for heat treatment.

High-grade unalloyed steels are those for which no consistent response to heat treatment and no purity requirements with respect to nonmetallic inclusions are specified. However, because of the stresses that arise in use, there are stricter or more numerous requirements compared with base steels, e.g., with respect to their fracture toughness, their grain size control, or their formability, so the manufacture of these steels requires special care.

High-grade alloy steels are for similar applications to those of high-grade *unalloyed* steels, but contain levels of alloying elements (to give special properties) that place them among the alloy steels (Table 23). They are in general unsuitable for quenching and tempering or surface hardening.

Special carbon steels are of higher purity than high-grade steels, and contain fewer nonmetallic inclusions. They are mostly intended for quenching and tempering or surface hardening, and show a consistent response to these treatments. A very wide range of working and application properties, e.g., high-strength or hardening properties within closely controlled limits, together with high specifications for toughness, forming and welding properties, are achieved by precise control of chemical composition, and by special care in manufacture and process control procedures.

Alloy special steels have an extremely wide range of working and application properties, achieved by precise control of chemical composition, and by special methods of manufacture and process control. This group includes steels

for structural engineering, pressure vessels, as well as mechanical engineering steels, stainless and heat-resistant steels, creep-resistant steels, steels for bearings and machine tools, steels with special physical properties, etc.

Steels can be classified according to their main characteristics and applications:

Flat products for cold forming
Structural steels
Steels for pressure vessels
Concrete reinforcing and prestressed concrete steels
Steels for rails
Free- cutting steels
Steels for wire drawing
Cold-heading steels
Engineering steels
Spring steels
Tool steels
Steels for packaging (tinplate, blackplate)
Welding filler materials
Stainless steels
Bearing steels
Steels with special physical properties

6.2.1.3. Definitions of Steel Products

According to DIN EN 10 079, steel products are defined according to their shape and dimensions, and/or their appearance and surface condition. There is no overall system; several classification systems exist in Europe. Definitions of the most important products are given below, and a more detailed subdivision is given in Table 24.

Liquid crude steel is steel as produced from its raw materials and ready for pouring. A distinction is made between liquid crude steel for ingot casting or continuous casting and for steel casting.

Solid crude steel is the product obtained by the solidification of liquid steel in a mold such that the product is suitable for subsequent forming.

Semifinished products are produced by strand casting (sometimes followed by rolling, forging, or cutting), by pressure casting, or by the rolling, forging, or cutting of blooms or slabs, and are generally suitable for further forming into flat or long products.

Flat products have an approximately rectangular cross section with width much greater than thickness. The surface is usually technically smooth, but can have regularly spaced indented or raised surface patterns, e.g., floor plates.

Long products have a constant cross section along their length, which is much greater than the width and height. The cross section usually complies with a standard specificaton. The surfaces of long products are technically smooth, but these too can have regularly spaced indented or raised surface patterns, e.g., for concrete reinforcing bars.

6.2.1.4. Designation Systems for Steel

Clear designation systems for steel grades are provided by the European Standards EN 10 027 (systems for naming steels) Part 1: codes (principal symbol) and ECISS Information Circular IC 10 (additional symbols for steel); and Part 2: numbering system.

The codes are formed from a principal symbol (Table 25) and an additional symbol, supplemented by numbers.

The steel numbers are formed according to the system given in Table 26. These correspond to the numerical classification used in Germany.

6.2.2. Types of Steel

6.2.2.1. Steels where the Mechanical Properties are Essential

Of the many properties of steel, its mechanical properties are the most relevant to its use as a material for the manufacture of commercial goods [574]. In many applications, other properties are also important, e.g., cold workability, suitability for heat treatment, resistance to corrosion and high temperatures, and machining properties. The mechanical properties are mostly asked for in the condition of delivery, but in many cases, they are obtained after further heat treatment or cold working by the customer.

Table 24. Classification of steel products

6.2.2.1.1. Normal- and High-Strength Structural and Reinforcing Steels

General. Steel grades used in structural steelwork, civil engineering, hydraulic engineering, bridge building, shipbuilding, offshore technology, pressure vessels, and many other applications in which climatic temperatures are important, are assessed by their strength and toughness at room temperature, and by their welding properties [575]. Normal-strength structural steels have minimum yield strength $< 355\,\mathrm{N/mm^2}$ in the as-rolled condition. Steels in this strength range are also supplied in the normalized condition. The usual normalizing process can be replaced by a temperature-controlled final roll pass, just above the normalizing temperature (thermomechanical treatment) which gives equivalent properties (delivery condition N). High-strength structural steels

Table 25. Principal symbols used in naming steels (DIN EN 10 027-1)

Symbol	Steel group	Characteristics
S	General structural steels (GS indicates cast steel)	Minimum yield strength, N/mm^2 for the smallest thickness range
P	Steels for pressure vessels (GP indicates cast steel)	Minimum yield strength, N/mm^2 for the smallest thickness range
L	Steels for pipelines	Minimum yield strength, N/mm^2 for the smallest thickness range
E	Engineering steels	Minimum yield strength, N/mm^2 for the smallest thickness range
B	Steels for reinforcing concrete	Minimum yield strength, N/mm^2 for the smallest thickness range
Y	Steels for prestressing concrete	Nominal tensile strength in N/mm^2
R	Rail steels	Minimum tensile strength, N/mm^2
H	Cold-rolled flat products of high-strength steels for cold forming	Minimum yield strength, N/mm^2
D	Flat products for cold forming	C = cold-rolled D = hot-rolled for immediate cold forming X = rolled condition (hot- or cold-rolled) not stated
T	Packaging sheets and strip	H = specified average Rockwell hardness for single reduced product; minimum yield strength, N/mm^2 for double-reduced product
M	Electric sheets and strip	Maximum hysteresis loss, W/kg
C	Unalloyed steels with average Mn content $< 1\,\%$, precluding machining steels (GC indicates cast steel)	Average C content $\times 100$
	Unalloyed steels with average Mn content $> 1\,\%$, unalloyed free-cutting steels, where the average content of each alloying element < 5 wt % (G indicates cast steel)	Specified average C content $\times 100$, followed by characteristic alloying elements with average content multiplied by the factor F Cr, Co, Mn, Ni, Si, W $F = 4$ Al, Be, Cu, No, Nb, Pb, Ta, Ti, V, Zr $F = 10$ Ce, N, P, S $F = 100$ B $F = 1000$
X	Alloy steels, where average content of at least one alloying element $\geq 5\,\%$ (GX indicates cast steel)	Specified average C content, followed by characteristic alloying elements and their average content
HS	High-speed steels	Average content of alloying elements in the order: W, Mo, V, Co

have minimum yield strength ≥ 355 N/mm^2. They are usually supplied in the normalized or thermomechanically rolled (TM) condition. Steels with minimum yield strength 500 – 880 N/mm^2 are usually supplied in the quenched and tempered condition, as the carbon content and alloying element content must be limited for weldability.

These steel grades are supplied in sheet, plates, beams, and merchant-bar stock. Steel grades in the quenched and tempered condition are supplied only as plates.

Steel products for incorporation in concrete are known as reinforcing steels [576]. These are of two types: those used in stress-free ferroconcrete, and prestressing steels, which are subjected to controlled prestressing, causing them to exert a compressive stress on the concrete [577]. The deadweight of the building itself and the load that it carries give rise to additional high tensile stresses in the steel rod or wire. The yield strength (and the 0.01 % offset yield strength for prestressing steels) is therefore the most important property of reinforcing steels. These steels are supplied in the as-rolled condition, though special temperature- controlled rolling and cooling is sometimes used. Quenched and tempered or cold-drawn wires are also very important prestressing steel products.

Reinforcing steels are used for buildings which are subject to the building regulations of individual countries. They require certification of public building authorities and are subjected to official continuous quality control.

Table 26. Steel groups *

	Unalloyed steels							
	Base steels		High-grade steels		Special steels	High-grade steels		Special steels
No.								Tool steels
0	00 90 base steels				10 steels with special physical properties			20 Cr
1			01 91 general structural steels with $R_m < 500$ N/mm²		11 structural, pressure vessel and engineering steels with C < 0.50%			21 Cr–Si Cr–Mn Cr–Mn–Si
2			02 92 other structural steels not intended for heat treatment with $R_m < 500$ N/mm²		12 structural, pressure vessel and engineering steels with C ≥ 0.50%			22 Cr–V Cr–V–Si Cr–V–Mn Cr–V–Mn–Si
3			03 93 steels with average C < 0.12% or $R_m < 400$ N/mm²		13 structural pressure vessel and engineering steels with special requirements			23 Cr–Mo Cr–Mo–V Mo–V
4			04 94 steels with average C ≥ 0.12% < 0.25% or $R_m \geq 400$ < 500 N/mm²		14			24 W Cr–W
5			05 95 steels with average C ≥ 0.25% < 0.55% or $R_m \geq 500$ < 700 N/mm²		15 tool steel			25 W–V Cr–W–V
6			06 96 steels with average C ≥ 0.55% or $R_m \geq 700$ N/mm²		16 tool steel			26 W excluding groups 24, 25 and 27
7			07 97 steels with higher P or S content		17 tool steel			27 with Ni
8					18 tool steel	08 98 steels with special physical properties		28 other
9					19	09 99 steels for other applications		29

* The classification of steel groups is in accordance with the classification of steels in EN 10020. The following information is provided: (a) steel group number, in upper left hand side; (b) principal characteristic of the steel group;

Alloy steels					
Miscellaneous steels	Stainless and heat resisting steels	Structural, pressure vessel and engineering steels			
30	40 stainless steel with < 2.5% Ni without Mo, Nb and Ti	50 Mn–Si–Cu	60 Cr–Ni with ≥ 2,0 < 3,0% Cr	70 Cr Cr–B	80 Cr–Si–Mo Cr–Si–Mn–Mo Cr–Si–Mo–V Cr–Si–Mn–Mo–V
31	41 stainless steel with < 2.5% Ni and Mo but without Nb and Ti	51 Mn–Si Mn–Cr	61	71 Cr–Si Cr–Mn Cr–Mn–B Cr–Si–Mn	81 Cr–Si–V Cr–Mn–V Cr–Si–Mn–V
32 high speed steel with Co	42	52 Mn–Cu Mn–V Si–V Mn–Si–V	62 Ni–Si Ni–Mn Ni–Cu	72 Cr–Mo with < 0.35% Mo Cr–Mo–B	82 Cr–Mo–W Cr–Mo–W–V
33 high speed steel without Co	43 stainless steel with ≥ 2.5% Ni without Mo, Nb and Ti	53 Mn–Ti Si–Ti	63 Ni–Mo Ni–Mo–Mn Ni–Mo–Cu Ni–Mo–V Ni–Mn–V	73 Cr–Mo with ≥ 0.35% Mo	83
34	44 stainless steel with ≥ 2.5% Ni with Mo but without Nb and Ti	54 Mo Nb, Ti, V, W	64	74	84 Cr–Si–Ti Cr–Mn–Ti Cr–Si–Mn–Ti
35 bearing steels	45 stainless steels with special additions	55 B Mn–B < 1.65% Mn	65 Cr–Ni–Mo with < 0.4% Mo + < 0.2% Ni	75 Cr–V with < 2.0% Cr	85 nitriding steels
36 Materials with special magnetic properties without Co	46 chemical resistant and high temp. Ni alloys	56 Ni	66 Cr–Ni–Mo with < 0.4% Mo + ≥ 2.0 < 3.5% Ni	76 Cr–V with ≥ 2.0% Cr	86
37 materials with special magnetic properties and with Co	47 heat-resistant steels with < 2.5% Ni	57 Cr–Ni with < 1.0% Cr	67 Cr–Ni–Mo with < 0.4% Mo + ≥ 3.5 < 5.0% Ni, or ≥ 0.4% Mo	77 Cr–Mo–V	87 steels not for heat treatment by user
38 materials with special physical properties without Ni	48 heat-resistant steels with ≥ 2.5% Ni	58 Cr–Ni with ≥ 1.0 < 1.5% Cr	68 Cr–Ni–V Cr–Ni–W Cr–Ni–V–W	78	88 high-strength weldable steels not intended for heat treatment by user
39 materials with special physical properties and with Ni	49 materials with elevated temperature properties	59 Cr–Ni with ≥ 1.5 < 2.0% Cr	69 Cr–Ni except groups 57 to 68	79 Cr–Mn–Mo Cr–Mn–Mo–V	89 high-strength weldable steels not intended for heat treatment by user

(c) R_m = tensile strength for high-grade steels. The limiting values for the chemical composition and tensile strength (R_m) are for guidance only.

Properties and Testing Methods. As a basis for the calculation of steel structures, values of yield strength and tensile strength are determined by tensile tests. If alternating mechanical stresses are expected to be applied to a component, e.g., in bridges or ships, the fatigue strength is important. Under some circumstances, fatigue strength is proportional to tensile strength. Deformability of strcutural steels under axial and multiaxial stress is assessed by tensile tests which give the percentage elongation after fracture, and sometimes the reduction in area at fracture.

Toughness and resistance to brittle fracture are determined by notched-bar impact energy tests at various temperatures, usually down to ca. − 60 °C. The values decrease more or less with temperature, sometimes irregularly. The important parameter, by international agreement, is the so- called transition temperature T_u, at which the Charpy V-notch impact energy falls to 27 J.

Many other test methods for toughness and crack arrest properties of steel have been developed, and form the basis of fracture mechanics. Examples inlcude V-notched tensile or bending test pieces taken from the full thickness of the plate, the Robertson test, which gives the crack arrest temperature (CAT) [578], or the drop weigth Pellini test, which gives the nil ductility transition (NDT) [579], [580].

Tensile tests, and the value derived from them, are also used to characterize reinforcing steels. For prestressing steels, the long-term behavior under static stress is important. This is determined either by a creep test (elongation under constant stress) or by a relaxation test (stress reduction at constant gauge length, with starting stress ca. 60 – 80 % of the measured tensile strength).

The metal-working properties are also very important. They influence the methods and costs of manufacture of components, e.g., cold or hot forming, welding, and flame cutting. Machinability is not so important for structural steels. Suitability for zinc coating may also be important. Flat products can be cold worked without difficulty by bending, bevelling, dishing, and other processes, the force required being determined by the yield strength. Changes to mechanical properties caused by work hardening must be borne in mind, as well as toughness reduction or yield strength reduction on cold forming under certain conditions (Bauschinger effect, see Section 6.1.2.1.2). After extensive cold forming, the mechanical properties can, if necessary, be restored to the starting condition by appropriate heat treatment, e.g., stress-free annealing. In hot forming, it is important to control the temperature before, during, and after the forming process if subsequent heat treatment is to be avoided. Thermomechanically rolled products cannot be heat treated, except by stress-free annealing, but this should only be carried out up to the temperature limit specified by the manufacturer.

Good welding properties are very important for structural steels. It must be possible to prepare defect-free welded joints at low cost, and these must have comparable load- carrying capacity to that of base material. The cost is influenced by the welding method, welding conditions, the choice of welding electrode, whether preheating is necessary and to what temperature. The latter depends on the cross-sectional thicknes of the weld, the grade of steel, and its chemical composition [581].

Figure 285. Lamellar tearing [583]

The chemical composition, especially the carbon content, the amount, shape, and distribution of sulfide inclusions, and the fineness of

grain determine the resistance to crack formation and propagation due to stresses arising during and after the welding process. These stresses, and the form and structure of the heat-affected zone in the base material near the weld seam, depend on welding data, e.g., heat input, working temperature, and cooling time from 800 to 500 °C ($t_{8/5}$) [582].

The overall aim is to limit the hardening in the region of the weld seam as much as possible, and to prevent grain growth in the heat-affected zone. Component design and the sequence of the various welds must ensure that the resulting stresses are as small as possible, and that there is no stress concentration (notch effect).

The test methods used to assess the suitability of a steel for welding are carried out on welded test pieces under standard conditions, and are the same as those described above for testing the base material for toughness and resistance to brittle fracture. To test the sensitivity of a steel to so-called lamellar tearing (Fig. 285) [583], when thick-walled items are to be welded, the mechanical properties are assessed by tensile tests in the thickness direction, and the reduction in area at fracture is determined (Z grades).

Grades of Steel. The most important steels in this group are the general-purpose structural steels. The starting point from which they were developed was rimming steel produced by the standard manufacturing processes of the early 1900s. In mainland Europe, basic converters were mainly used (basic Bessemer or Thomas steel), and in Britain and the United States the open hearth process (Siemens–Martin steel) was used almost exclusively. The differences in carbon content due to differences in steelmaking processes led to the production of two grades of steel with similar structures, both with a ferrite matrix, but differing in pearlite content and in the levels of other elements (P and N). The Thomas process produced a steel containing ca. 0.10 % C, the tensile strength of the rolled product being 365 N/mm^2 (St 37, now referred to as Fe 360 in EN 10 025); and the Siemens–Martin process produced a steel containing ca. 0.16 % C, with tensile strength 400 N/mm^2 like ASTM-A36 or grade A shipbuilding steel.

Rimming steels are hardly used today as structural steels, as the unavoidable segregation greatly interferes with the weldability, and they cannot be strand cast. The basic oxygen steelmaking process which predominates today results in a chemical composition which gives tensile strength ≥ 360 N/mm^2, and good weldability, no special metallurgical techniques being necessary.

In all grades of structural steel, yield strength depends on thickness. Fe 360 steel, which has minimum yield strength 235 N/mm^2 up to 16 mm thick, is still very important.

The effort to improve the efficiency of steel structures, i.e., to increase the useful load for a given mass of the load-carrying component, led in the early 1930s to the development of a weldable structural steel with yield strength ≥ 355 N/mm^2, and tensile strength ≥ 510 N/mm^2. This product, Fe 510 (EN 10 025), contains ≤ 0.2 % C, ≤ 1.6 % Mn, and ≤ 0.55 % Si, is a low-alloy steel, and is mostly produced with a fine grain, i.e., with Al added for fixation of nitrogen.

A steel intermediate between Fe 360 and Fe 510, with tensile strength ≥ 400 N/mm^2 and yield strength ≥ 235 N/mm^2 for all thicknesses, is still of great importance in shipbuilding. However, Fe 430 is little used as a general-purpose structural steel.

Figure 286. Development of the minimum yield strength of structural steels

Steels with improved toughness and welding properties are available in several quality groups (e.g., groups B to DD in EN 10 025), and are supplied in the as-rolled or normalized condition. These quality groups differ in the temperature

used for measuring the notched-bar impact energy, a higher minimum value for this quantity being specified for quality group DD.

In the 1960s, structural steels were further developed for use in very highly stressed components, e.g., bridges, lock gates, storage tanks, leading to the weldable fine-grained structural steels (EN 10 113), which are supplied in the normalized or thermomechanically rolled condition. These have minimum yield strength 275 – 460 N/mm^2. With reduced carbon content, these steel grades can be low-alloyed, and contain Al, with small additions of carbonitride-forming elements, e.g., niobium. This leads to improved strength properties via a very fine-grained structure and precipitation hardening.

Figure 287. Maximum achievable hardness of martensite as a function of carbon content

Offshore technology, especially in the North Sea, requires steels with yield strength $\geq$ 355 N/mm^2 with further improvements in toughness and weldability, e.g., a sharp limitation on the hardness values in the heat-affected zone of a weld seam. Further reductions in carbon and sulfur content led to the costly offshore steels [584], which may be alloyed with Nb or other microalloying elements (e.g., Ti or V), sometimes with small additions of Cu and Ni. More stringent standards are specified in EN 10 225 for these steels.

Figure 288. Tempering diagram of a heat-treatable steel after quenching from 830 °C in water
Diameter 60 mm

The development of quenched and tempered steels with good toughness and welding properties for use in structural work has resulted in steels with minimum yield strength up to 900 N/mm^2 (Fig. 286) [585]. These can be used very economically for applications where weight saving is very important, e.g., in mobile cranes, heavy commercial vehicles, and in supports for mine workings [586]. Carbon content has been reduced, and the steels are alloyed, so that, on quenching, the austenite is transformed into martensite or bainite over the whole cross section.

Within this group of water-quenched and tempered structural steels, a steel grade with yield strength $\geq$ 690 N/mm^2 is most important, as good toughness and welding properties have been achieved with only small additions of alloying elements. For mobile cranes with high carrying capacity, a steel with minimum yield strength 890 N/mm^2 is widely used. In offshore technology and shipbuilding, water-quenched structural steels with minimum yield strength 420 and 460 N/mm^2 are preferred; for general-purpose structural steelwork, the cheaper normalized or thermomechanically treated grades of steel are used.

The development of low-pearlite, thermomechanically treated high-strength structural steels, produced in the form of wide strip, up to 18 mm thick, is discussed later, as these are important for their cold forming properties as well as their mechanical properties.

Finally, the weatherproof steels must be mentioned. The presence of chromium and copper in these steels gives them improved resistance to atmospheric corrosion; they have similar structures and mechanical properties to those of Fe 360 and Fe 510 steels. On unprotected weathering, these steels form surface layers, whose structure, formation time, and protective action vary with different kinds of atmospheric action. For their successful and economic use, the design must be appropriate to the material, as specified in EN 10 155 [587].

Table 27 lists the most important structural steels, with their essential characteristics. Only a general overview of these can be given here.

The specifications for concrete-reinforcing steels have been greatly uprated compared with those for the earlier product, Monier iron. Continuing efforts to save weight have led to smaller sections, with considerably increased yield strengths. EN 10 080 specifies two products BSt 420 and BSt 500, with minimum yield strength 420 and 500 N/mm^2, respectively. These values can be achieved for different rod diameters with steels of approximately the same chemical composition by microalloying, cold working, or controlled cooling after hot rolling [588]. The stability of the structure depends on the total effect of the rods embedded in the concrete, not on the tensile properties of the individual rods. Tensile testing is therefore a statistical process; within a production batch, 5 % of the rods may fall below the minimum value in a normal distribution.

If tack or butt welding is used, the suitability of the material for these processes must be confirmed.

Steels used in prestressed concrete must have considerably better properties. Steel grades for $\leq$ 36 mm diameter rods should have 0.2 % proof strength 1080 N/mm^2, with tensile strength 1230 N/mm^2, and 0.01 % offset yield strength 950 N/mm^2. For wire, depending on the diameter, 0.2 % proof strength 1420 N/mm^2 in the quenched and tempered state and 1570 N/mm^2 in the cold-drawn state is specified. Braided or stranded cold-drawn wire is also used in prestressed concrete. Quality specifications for prestressing steels are given in EN 10 138.

6.2.2.1.2. Steels Suitable for Heat-Treatment and Surface Hardening [589]

General. The effect of structure on the properties of steel has been described in Section 6.1. The explanation for the wide range of properties that can be produced by heat treatment is that two phase transformations occur in the iron lattice between the melting point and room temperature. This enables a large number of different structures to be produced, depending on the chemical composition and the type of heat treatment (see Section 6.1.3).

In steels intended for quenching and tempering or similar heat treatment, strength and toughness properties are of overriding importance [590], as is the case with the structural steels described in Section 6.2.2.1.1. However, other properties, described as important in the

Table 27. Important normal- and high-strength structural steels

Grade	Standard specification	Delivery condition	Yield strength, N/mm^2	Tensile strength, N/mm^2	Elongation, %	Notched-bar impact energy, J *	Testing temperature, °C
S 235 J2 G3	EN 10 025	N	$\geq$ 235	340 – 470	24	27	– 20

earlier section, e.g., weldability, are not so vital. Hence, it is not necessary from the outset to consider limiting the carbon content. On the contrary, high carbon content is always considered in these steels, as their strengths need to be high, sometimes extremely high. In spite of certain transitions, the carbon content is the important difference from the weldable quenched and tempered steels described earlier.

As described in Section 6.1.3.2 this heat tretment consists of quench hardening in the first step. The material is heated until transformation to austenite is just complete and then it is quenched so rapidly that during cooling the austenite is not transformed to ferrite and perlite, but to martensite. Figure 287 shows the hardness values that can be achieved by complete transformation to martensite, as a function of carbon content.

In a second step, the hardened workpiece is tempered, i.e., reheated to a temperature appreciably below that at which the first γ solid solution reappears. This enables carbon to be released from forced solution in the martensite, and the dislocation density, which had been increased by the hardening, decreases again. This process can be very precisely controlled by means of the temperature and duration of the tempering stage, enabling the desired properties to be obtained (Fig. 288).

Quenched and tempered steels have a wide range of uses: as components of vehicles and machines, in heavy forgings, in springs and roller bearings, and in a wide range of tool steels. In general, the carbon content is 0.25 – 1 % or above. Depending on the application they are unalloyed, but mostly have alloy content $<$ ca. 5 % (low-alloy steels). Tool steels, which have a very wide range of applications and are frequently highly alloyed, do not come within the scope of this article [591].

Properties and their Measurement. For the steels discussed in this section, the distinction must be made between the application properties and the processing properties.

When steel is in use, strength, hardness, and toughness are important, but requirements vary widely according to the loading conditions in individual cases. The fatigue endurance limit is important in many applications, and a very high degree of purity with respect to nonmetallic inclusions can also be extremely important (springs, roller bearings).

Surface decarburization can be tolerated only within very narrow limits, so that, for high carbon content, great care in hot forming processes and subsequent heat treatment is necessary. With steels in which special carbides are present (Cr, Mo, V), the conditions must ensure uniform carbide distribution in the structure in all stages of steel manufacture.

The demand for these application properties means that the values determined in tensile tests are very important. The area reduction at fracture Z is of great interest when assessing these materials.

The notched-bar impact energy is usually determined at room temperature with the ISO V-notched specimen, which has replaced U-notched (e.g., DVM) test pieces. However, the DVM test piece is still used in some cases, and was predominantly used to obtain the results quoted in the literature.

The Rockwell test (HRC) is the most common method of hardness measurement, especially for high hardness values.

Metallographic investigation of purity, metal structure, and carbide distribution (if applicable) is essential with these steels.

The most important processing property is hardenability, the tendency of a steel to increase in hardness on quenching. The highest hardness value attainable on complete transformation to martensite (Fig. 287) depends on the carbon content; the extent of hardness penetration depth (partial conversion to martensite) depends on the overall chemical composition of the steel.

Of the numerous methods of testing hardenability, only Jominy's end quench test is now of practical importance [592]. The cylindrical test piece is heated to the hardening temperature (Fig. 289), and one end face is quenched by a standard water jet [593]. The extent of hardening is determined by observing a polished side surface. The hardness values at various distances from the quenched end face (Fig. 290) give a measure of the hardenability of the steel. These end quench hardness curves, which show a small amount of scatter, are the most important criteria for the assessment and classification of hardenable steels in all standard specifications. In conjunction with the TTT diagrams (see Section 6.1.3.1) for the various grades of steel, the

hardening curves facilitate the choice of the most suitable and economic steel grade for a given application and with a given section, and the conditions of the heat treatment. As the hardenability, so defined, is a function of the chemical composition and the steel making process, formulas have been developed for different alloy types which can be used to calculate end quench hardness curves [594].

Figure 289. The end quench test

In addition to hardenability, other important processing properties include the capacity for cold shearing of semifinished products and merchant bars, machinability, and massive cold forming properties. If weldability is needed, e.g., for joining structural elements, a suitable welding process must be used, with low heat input or high energy density.

Capacity for cold shearing can be ensured only by spheroidize annealing appropriate grades of steel (> 0.4 % C), while machinability (see Section 6.2.2.4.3) can be improved by a small increase in sulfur content, and sometimes by a small addition of lead. Massive cold forming properties can sometimes be improved by adjusting the chemical composition (see Section 6.2.2.4.3).

Steel Grades. Whereas heat-treatable unalloyed steels, usually with carbon content varying stepwise from 0.2 % (2 C 22) to 0.6 % (2 C 60) are similar worldwide, alloyed heat-treatable steels have been developed in the industrialized countries to varying extents, depending on the availability and cost of the expensive alloying elements, e.g., nickel. The resulting range of heat-treatable steels specified in EN 10 083-1, ISO/R 683, and the SAE Handbook, whose areas of use sometimes overlap, cannot be described in detail here [595]. They include, in order of increasing capacity, the Cr, Cr – Mo, and Cr – Ni – Mo steel grades.

Heat-treatable steels which also contain the alloying elements vanadium or cobalt can have yield and tensile strengths $\gg$1200 N/mm^2, with good toughness properties. These are known as ultra-high-strength steels (UHS steels), and are used for components where the cross section must be as small as possible. e.g., in the aerospace industry [596]. This group also includes very highly alloyed maraging steels; these are not described further here.

For surface hardening, in which a completely martensitic structure is formed in only a controlled surface layer while the structure of the inner core is unchanged, unalloyed steels or steels alloyed with chromium only are preferred, as the hardenability curves of these materials are relatively steep.

Brief mention should be made of the development of precipitation-hardened ferritic – pearlitic steels (PFP steels), which are used for forged components, mainly in the automotive industry [597]. These microalloyed steels are subjected to a thermomechanical treatment by controlled cooling from the forging temperature, and can replace "classical" quenched and tempered steels, enabling the manufacturing costs of items such as steering stub axles, front axle components for commercial vehicles, and inlet valves for combustion engines to be much reduced by the avoidance of heating costs (Fig. 291), and by other processing simplifications [598].

Figure 290. End quench hardness curves for heat-treatable steels of various chemical compositions
A) Carbon content approximately constant, variable alloy content; B) Alloy content approximately constant, variable carbon content

Figure 291. Processes in the production of crank shafts from various steels
A) Heat-treatable steels; B) Microalloyed pearlitic steels

These steels have carbon content ca. 0.25 – 0.45 %, with Mn content 1.2 – 1.6 %, and contain 0.1 % vanadium (or sometimes niobium). Components can have tensile strength 850 N/mm^2 (27 Mn Si V S 6), or 1000 N/mm^2 (44 Mn Si V S 6), combined with good toughness properties. Development work on these steels and their possible applications is expected to lead to further improvements.

Most spring steels are quenched and tempered steels [599]. Steels containing 1.5 – 2 % Si that were formerly widely used for springs have lost much of their importance because of their strong tendency to surface decarburization, except in cases where the surface quality has to be improved by machining after heat treatment. Heat treatable steels used for springs mostly have carbon content > 0.5 %.

Case Hardening Steels. These are designed for a heat treatment similar to quenching and tempering, but with a different objective, which can be compared to the surface hardening process [600].

Components made of these steels, with carbon content 0.10 – 0.25 %, are carburized by total or partial immersion in powder, or in a molten salt bath, or a gas atmosphere. This can give carbon content > 1 % in the surface layer. After the component has been case hardened, it is tempered at comparatively low temperature (ca. 200 °C). This produces a very hard surface layer and a less hard but very tough interior, resulting in high wear resistance, improved fatigue strength, and very good resistance to impact stresses.

The chemical composition of case hardening steels must be such that good carburization is possible without the formation of a coarse-grained structure at the temperatures used. Components made of case hardening steel are often produced in large numbers, e.g., gear wheels for motor vehicles, so there must be a high degree of uniformity within a melt and from one melt to the next. Plain carbon steels can be used, but usually low- to medium-alloy steels, containing Cr,Cr – Mn,Cr – Mo,or Cr – Ni – Mo, are utilized.

In the United States, case hardening steels are also widely used for roller bearings, but in Europe, highly through-hardening steels containing ca. 1 % C are preferred [601]. These steels are alloyed with ca. 1.5 % Cr. For larger dimensions, the Cr content is increased to ca. 1.8 %, with addition of ca. 0.3 % Mo.

Hardness, wear resistance, and fatigue strength are the most important qualities of roller bearing steels. After quench hardening, stress relief is usually carried out at < 200 °C. The high specifications for purity and metal structure, especially with respect to the carbide structure, have already been described.

6.2.2.1.3. Steels for Elevated Temperature Applications

General. Creep-resistant steels must have strength properties and ductility appropriate for the high operating temperatures expected in use. Many components, e.g., for the high-pressure systems of thermal power stations, are used at an almost constant operating temperature and constant mechanical load. For this type of design, statically determined characteristic properties are used, including the hot yield strength at up to ca. 400 °C, and the creep strain limit or creep rupture strength above this temperature. For fluctuating mechanical and thermal stresses, dynamically determined characteristic properties are used, and the number of cycles of high load (e.g., emergency shutdowns) is limited during the component lifetime. To avoid crack formation in the case of impact loads, the toughness properties must be adequate, both in the material as supplied and after it has undergone prolonged thermal exposure. A material must have good high-temperature corrosion resistance in the medium (gas, air, steam) at the operating temperature.

Properties and Their Measurement. As the temperature increases, the yield strength and tensile strength values determined in tensile tests on metallic materials decrease. At higher temperatures, the mechanical strength is so strongly time dependent that the creep strain limit and creep rupture strength can be less than the hot yield strength.

Figure 292. Creep rupture stength of 12 Cr 1 Mo V steel A) At 550 °C; B) At 600 °C

Reliable characteristic parameters for design lifetimes > 200 000 h, e.g., for power stations, can only be determined by very prolonged creep rupture tests. A time extrapolation of test results of this kind by a factor > 3 is not meaningful [602], [603]. Experiments lasting at least 8 years with a large number of test pieces from different heats at various temperatures are required to ensure that the figures for a new material are known with certainty for design purposes (Fig. 292) [604]. Creep tests on welds, in some cases in the intended environment, are also required. Tests in aggressive gases, or in reactor helium [605], greatly increase the cost compared with normal testing in air. If the hot yield strength and creep rupture strength are plotted against the test temperature for a material, the hot yield strength curve intersects that of the creep rupture strength. This intersection point (Fig. 293) [606], indicates the temperature up to which the component design can be based on the material's hot yield strength. For design temperatures above the intersection point, calculations must be based on the creep rupture strength. According to the German technical regulation for steam vessels, TRD Series 100, the lowest of the following figures is critical when calculating the highest operating temperature:

1) Hot yield strength:	$\frac{R_{p\,0.2}}{1.5}$
2) Creep strain limit:	$\sigma_{1/100000}$
3) Creep rupture strength	
at 100 000 h:	$\frac{\sigma_{B/100000}}{1.5}$
at 200 000 h:	$0.8\,\sigma_{B/200000}$

Figure 293. Hot strength values according to DIN 17 175
a) St 35.8; b) 17 Mn 4; c) 15 Mo 3; d) 15 Ni Cu Mo Nb 5; e) 13 Cr Mo 4 4; f) 10 Cr Mo 9 10; g) X 20 Cr Mo V 12 1

The minimum values of the hot yield strength and the recommended values of creep strain limit and creep rupture strength are specified as a function of temperature in the most recent issues of DIN 17 155 for heavy boiler plate, DIN 17 175 for seamless tubes, DIN 17 177 for longitudinally welded tubes, DIN 17 240 for nuts and bolts, and Stahl – Eisen Werkstoffblatt (StEW) 670 for high-temperature steels.

Similar regulations apply in other countries. In the United States, the ASME Code gives allowable stresses as a function of temperature for every material. This is based on the lowest of the following figures:

1) Tensile strength at 20 °C:	$\frac{R_m}{4}$
2) Hot yield strength:	$\frac{R_{p\,0.2}}{1.5}$
3) Creep rupture strength:	$\frac{\sigma_{B/100000}}{1.5}$

For internationally used high-temperature and creep-resistant steels, the characteristic high-temperature strength values have been harmonized by agreement between the national committees. However, for newly developed steels, the creep rupture values available from some countries should be viewed critically, as they may be based on extrapolations by a factor of $\gg 3$, and hence may be too high.

As well as the creep measurements mentioned, isothermal relaxation experiments at high temperatures are carried out for screw stock.

Toughness behavior has so far been assessed from the reduction in area and elongation at fracture measured on creep rupture specimens, and the behavior of notched creep rupture specimens. Good performance properties are postulated if the observed figures for notched test pieces lie within the same scatter band as that for unnotched pieces, or in the upper part of it (Fig. 294) [607], [608]. In future, additional figures obtained in fracture mechanical tests at room temperature and elevated temperatures are to be included in the assessment, and the possibility of embrittlement of the material on prolonged stressing of the component is to be considered.

Figure 294. Creep rupture strength at 650 °C of X 3 Cr Ni Mo N 17 13 steel
K, notched sample; arrow, still flowing

Unlike components made of most other types of material, those made of creep-resistant steels are assessed for their remaining life expectancy after various periods of time. Such assessments can be carried out if the lifetime assumed in the design calculations is exceeded, if other design assumptions (pressure, temperature) are changed, or if other components have not withstood similar stresses [609], [610]. In Germany, TRD 508 specifies procedures in such cases.

Grades of Steel. *Plain carbon steels* have been used since the 1900s for temperatures up to ca. 400 °C and low mechanical stresses. To meet the increased demands on the mechanical load-bearing properties of power station components, fine-grained structural steels with improved high-temperature properties have been developed. Their carbon content has been reduced to $< 0.20\,\%$, or even $< 0.15\,\%$, to improve their toughness and to limit hardening in heat-affected zones. They contain $\leq 2\,\%$ manganese and small additions of aluminum, vanadium, niobium, and nitrogen in various combinations to give increased strength by grain refinement. Depending on the trend of development, the hot yield strength can be increased by small additions of molybdenum, nickel, and copper. This group of materials includes normalized ferritic – pearlitic steels and heat-treated bainitic steels. These steels are used for pressure-bearing parts of nuclear power stations, and also in conventional power stations for pressure feedwater pipes, cylindrical boiler shells, etc. (Fig. 295) [611]. There are also areas of application in the chemical and petrochemical industries. These steels are normally used only in the temperature range in which hot yield strength is the design criterion.

Figure 295. Areas of application of high-temperature steels
LWR = Light water reactor

Mainly as a result of the safety requirements of the nuclear industry, further developments to these steels have been directed to improving their toughness properties. Important developments have included reduction of the carbon content, and strength improvement by the addition of manganese, nickel, and molybdenum (e.g., 15 MnNi 6 3, 15 NiCuMoNb 5, and 20 MnMoNi 5 5 steels). By reducing the sulfur content and chemically bonding the remaining sulfur, a significant increase in toughness can be achieved, especially perpendicular to the direction of rolling [612].

Low-Alloy Steels for Creep Resistance. Molybdenum is the alloying element that most effectively increases creep resistance in this group of steels. The greatest effect is observed at 0.5 % Mo [613]. The oldest creep-resistant alloy steel in Germany is 15 Mo 3 steel, alloyed with 0.3 % Mo to prevent long-term embrittlement. In the United States, Mo content 0.5 % is usual in the steel grade T 1. After heat treatment, molybdenum steel has a ferritic – pearlitic structure. It is mainly used in the temperature range 400 – 500 °C.

Figure 296. Change of impact strength at room temperature after long-term high-temperature exposure (550 °C)
a) 17Cr-13Ni-2Mo N; b) 16Cr-13Ni-1Mo V Cb N; c) 12Cr-1Mo V; d) 2.25Cr-1Mo; e) 1Cr-0.5Mo

The long-term embrittlement of Mo-containing steels above 440 °C can be prevented by alloying with chromium [614]. This discovery led to the development of stronger creep-resistant steels with molybdenum content up to about 1 %. The steels 13 CrMo 44 and 10 CrMo 9 10, which correspond to the United States steels T 12 and T 22, resulted from this development, and have been used successfully

all over the world in the temperature range 450 – 550 °C (Fig. 295). Depending on size, shape, and heat treatment, these steels have variable ferrite and bainite content. Chromium contributes only slightly to the creep strength, but improves scaling resistance.

Increasingly strict safety requirements are leading to high specifications for toughness properties and creep rupture strengths for these steels. However, in the course of a prolonged period of stress, the toughness of components can decrease to a greater or lesser extent according to the stability of the structure of the material (Fig. 296) [611]. This behavior cannot be changed by metallurgical treatment of the heat.

Martensitic Steels with Higher Chromium Content for Creep Resistance. As power station design develops, the tendency is towards larger units, higher temperatures, and higher pressures. This has led to highly stressed components such as live steam pipework, for which low-alloy steels with very thick walls are used. The development of steels with higher strength and higher creep resistance containing 9 – 12 % chromium, with additions of molybdenum, vanadium, nickel, and niobium, offers the possibility of using lighter and more flexible designs, even for these highly stressed areas (Fig. 297). After heat treatment, these steels have the tempered martensite structure, even with wall thickness as high as 100 mm.

Figure 297. Dimensions of comparable T-pieces in 10 CrMo 9 10 and X 20 CrMoV 12 1

In Europe, a 12 % chromium steel with the German grade number CX 20 CrMoV 12 1 has been used for some decades with great success. Its high carbon content (0.20 %) leads to a fairly high degree of hardening on hot processing or welding, reaching ca. 600 HV. With appropriate temperature control, this steel is included in the program of all European fabricating plants. To facilitate metal-working processes, a 9 % chromium steel with carbon content reduced to 0.10 % was developed in the 1980s [615]. This reaches only ca. 420 HV after hardening [616]. In the United States, this is known as T 91 or P 91 steel, and, in Germany, X 10 CrMoVNb 91. Control of the alloy content within narrow limits and especially the precipitation of very finely divided niobium carbide gives creep rupture strengths in the important temperature range 550 – 600 °C that are 10 – 30 % better than those of X 20 CrMoV 12 1 steel.

As these martensitic steels have the advantage of lower thermal expansion and higher thermal conductivity compared with the austenitic steels used at ca. 600 °C, development programs are in progress, aimed at increasing the creep rupture strength of martensitic steels still further.

As the carbon is in the form of very stable carbides in these steels, they also meet the demanding requirement for resistance to high-pressure hydrogen for the chemical and petrochemical industries.

Austenitic Steels for Creep Resistance. Austenitic Cr – Ni steels are used for operating temperatures $\geq$ 600 °C (Fig. 295). To avoid embrittlement at the operating temperature (σ-phase), these steels are produced with higher nickel and lower chromium content than the stainless grades, e.g., 16 % Cr and 13 % Ni. Addition of N, Mo, W, V, Co, Nb, Ti, Al, or B, individually or in combination, significantly increases the creep strength of these steels.

Unstabilized austenite was at first favored for boiler construction in the United States, but niobium-stabilized austenites were later developed in Germany to reduce the risk of intercrystalline corrosion, and to improve creep resistance; they have been used with great success [607].

In order to produce crack-free welds on even larger sections, a series of unstabilized austenites with much reduced carbon content were developed in Germany at the end of the 1960s [608], [617]. Addition of ca. 0.15 % N compensated for

the lack of niobium, whose presence improves creep rupture strength (Fig. 294).

Austenites with additions of W, Ti, B, and Co were used to meet still higher specifications for creep strength and operating temperatures. For weldable components, boron content is tolerable only up to a maximum of 0.006 %. Steels with cobalt additions of 10 – 20 % [618] give the highest creep rupture strengths above 650 °C. These are used in the construction of gas turbines and power transmission systems. They represent the transition to the high-temperature nickel and cobalt alloys, both in composition and use.

Standardization. Testing procedures at high temperatures are described in EN 10 002-5. The European standard EN 10 028-2 gives a more detailed specification for high-temperature sheet steels, EN 10 216-2 for seamless tubes, EN 10 217-2 for welded tubes, EN 10 222-2 for forgings, and EN 10 213-2 for steel castings. The following United States standards give specifications for high-temperature steels: for sheet, ASTM A 202, A 203, A 204, A 225, A 299, A 302, A 387, A 515, A 516, A 517; for seamless tubes, ASTM A 106, A 161, A 192, A 209, A 210, A 213, A 271, A 335, A 369, A 376, A 426, A 430; for welded tubes, ASTM A 178, A 226, A 249, A 250, A 358, A 671, A 672, A 691; for forgings, ASTM A 105, A 182; for bolts, ASTM A 193; and for nuts, ASTM A 194.

6.2.2.1.4. Low-Temperature Steels

General. Low-temperature steels must have good toughness properties at the lowest planned operating temperature. In cryogenics, gas separation, liquefaction of hydrocarbons, space technology, superconductivity, and other areas, components are subjected to temperatures of − 200 °C and below [619]. These components and their welded joints must have good toughness properties, especially under impact stress, to avoid brittle fracture.

Properties and Tests. Yield strengths and tensile strengths, which are measured by tensile tests, increase with decreasing temperature. With ferritic steels, a decrease in toughness occurs over the narrow temperature range (transition temperature) typical of these grades of steel. At temperatures below the transition temperature, which also depends on the testing method, the test pieces show brittle fracture properties. The transition temperature is shifted to higher temperatures by an increasing degree of multiaxial stress, a sharper notch shape, and a higher rate of loading. Stable austenitic steels show a small decrease in toughness properties with falling temperature, but with no sudden drop.

Toughness measurements are carried out by means of notched-bar impact tests, preferably with the ISO V-notch test piece at a low temperature typical for the material, or at the lowest planned component temperature. The tests must be carried out not only on the base material, but also on the welded joint, the weld metal, and the heat-affected zone. For a fundamental assessment of the material, tests must also be carried out on test pieces similar in size and shape to the component.

Other important application properties include the thermal expansion coefficient and the thermal conductivity [620]. These play an important part in control of shrinkage stresses in long pipes or rigid structures on cooling to the operating temperature, and also when different materials are joined, e.g., when ferritic steels are welded with an austenitic material. Shrinkage stresses in pipework are reduced by compensators, whose capacity and number depend on the thermal expansion coefficient of the steel, the operating temperature, and the length of the pipeline. Shrinkage of austenitic steels is 50 % greater than that of ferritic steels.

Ferritic Steels. Within the range of world climatic temperatures and a little below this, i.e., down to ca. − 50 °C, normalized plain carbon fine-grained structural steels meet toughness requirements. Addition of ≤ 1.7 % Mn and ≤ 0.8 % Ni, with carbon content reduced to 0.16 %, increase both yield strength and toughness within this temperature range. These steels are suitable for propane and propene liquefied gas technology, i.e., for operating temperatures down to − 50 °C.

For lower temperatures, several nickel-containing steels have been developed. Nickel reduces the transition temperature, and favors formation of bainite and martensite. Both these effects lead to a reduction in the size of

the secondary grains. Heat treatment involving quenching and tempering further enhances this effect, and leads to a significant reduction in ductile–brittle transition temperature. Thus, steels containing 3.5 % Ni can be used at − 100 °C, and those containing 5 % Ni down to − 120 °C (below the liquefaction temperatures of carbon dioxide, ethane, and ethene). Steel containing 5.5 % Ni and 0.2 % Mo is a later development which gives improved toughness properties, enabling it to be used even at − 170 °C.

Steel containing 9 % Ni represents a special case. It has outstanding toughness properties even at − 200 °C, and is widely used in natural gas and air liquefaction. Compared with the austenitic steels used in this temperature range, 9 % Ni steel has twice the yield strength and therefore enables designs with smaller load-bearing sections to be used. A further advantage over austenitic steels is the significantly lower thermal expansion coefficient of 9 % Ni steel, enabling the number of compensators in long pipelines subjected to low temperatures to be reduced. On cooling from room temperature to − 200 °C, a 1 km pipe of austenitic steel shrinks by 3 m, while 9 % Ni steel shrinks by only 2 m. This steel also has a special structure. On normalizing by cooling with air or water, a transformation structure of low-carbon martensite with some bainite is at first formed. Subsequent tempering is carried out just above A_{c1}. This produces small amounts of stable austenite in the transformation structure, and these give the toughness properties [621].

In all low-temperature ferritic steels, the sulfur content should be minimized to give optimum toughness properties, and to reduce toughness anisotropy. With 3 % Ni steel, matching welding consumables can be used. The higher-nickel steels are welded with austenitic filler materials. These can be iron-based alloys with ca. 18 % Cr, 12 % Ni, or nickel-based materials with ca. 65 % Ni and 15 % Cr. The lower yield strength of the austenitic weld metal compared with the ferritic base material must be allowed for in designing the component. When austenitic weld materials containing 18 % Cr and 12 % Ni are used, the welded joint must not be heat treated, to avoid diffusion of carbon from the base material into the weld metal. To overcome these problems, a type of welding material containing 11 % Ni has been developed which gives good toughness properties at − 196 °C, and has strength properties that match the base material (Fig. 298) [622], [623].

Austenitic Steels. Austenitic Cr–Ni steels are suitable for operating temperatures close to absolute zero (−273 °C). To optimize toughness properties, the alloy content must be such that a stable austenitic structure is produced, and no martensite is formed by plastic deformation at these low temperatures. These steels are also used in superconductivity technology, as they have no ferromagnetic constituents, even at the lowest temperatures. This is also true for the welded joints, whose freedom from hot cracking (a common occurrence otherwise) must be ensured by including small amounts of ferrite. A stable austenitic steel with a high nickel content and additions of Mo, Mn, and N has proved successful [624]. It also shows a higher yield strength than nitrogen-free austenitic steels (Fig. 299).

Whereas austenitic Cr–Ni steels have a relatively high thermal expansion coefficient, that of austenitic steel containing 36 % Ni is extremely low, ca. 10 % of the value for normal austenites. This material also maintains its good toughness properties near absolute zero. It is therefore suitable for low-temperature components where it would be difficult to design a shrinkage compensation system, or where sudden temperature changes are to be expected. Examples of its use include membrane tanks for liquefied gas tankers and components for filling plants in rocket technology [625].

Standards. Specifications for low-temperature steels are provided by European standards EN 10 028-4 for nickel-steel sheet and EN 10 213-3 for steel castings. The United States ASTM standards include specifications for low-temperature steels as follows: for sheets, ASTM A 320, A 516, A 537, A 553; for pipes, ASTM A 333, A 334; for screws, ASTM A 320; for welded components, ASTM A 350, A 420, A 522.

6.2.2.1.5. Wear-Resistant Steels [626]

General. Wear occurs as a result of the mechanical interaction of two bodies in contact

Figure 298. Properties of weld metals for X 8 Ni 9 steel
A) Strength properties; B) Notched-bar impact energySMA = shielded-metal arc welding; MIG = metal – inert gas welding; SA = submerged-arc welding; TIG = tungsten inert-gas welding

which move relative to each other, so that their surfaces become eroded and altered (see also → Abrasion and Erosion). The surface properties of a material subjected to wear, e.g., during the dressing and transporting of granular mineral materials, are therfore of the greatest importance. The nature of the wear system is also very important, e.g., dry or lubricated sliding wear, dry or lubricated rolling wear, jet wear, or other mechanisms. Thus, wear depends not only on the material of the main constructional component, but also on all the other materials that make up the system, and on other conditions. Assessment of the suitability of a material by means of laboratory wear tests is problematic [627]. Tests of this type, e.g., by rotary grinding mills or the impact of a stream of abrasive particles, should be used only for basic research. The evaluation of different iron-based materials for a particular use requires practical investigation of the actual system.

Properties and Methods of Measurement. As wear is a surface problem, surface hardness

Figure 299. Low-temperature mechanical properties of plate and rod 12 – 80 mm thick
A) X 3 CrNiN 18 10 steel; B) X 3 CrNiMoN 18 14 steelTensile test pieces from plate: transverse; from rod (80 mm square): longitudinal; notched-bar impact test pieces: ISO V-notch transverse; notch-tensile test pieces: $\alpha_k = 4$

is the most important property to be measured. However, when hardness properties are equal, differences in structure can affect wear behavior [628]. Therefore, as well as surface hardness measurements, investigations of metallic structure are carried out. This gives information about the proportions of the various very hard particles in the structure, not only in the surface layer, but also in the cross section, giving the depth to which wear can be tolerated in a component. With steels that are only quench hardened, and also with quenched and tempered hypoeutectoid steels, increased carbon content leads to increased hardness values, and hence higher wear resistance properties. Carbides are responsible for wear resistance in most hypereutectoid steels which are normalized or quenched and only slightly tempered.

Grades of Steel. In quenched ledeburitic steels (> ca. 1.5 % C) and in martensitic white cast iron, resistance to abrasive wear is maximized at the expense of toughness, and hence of resistance to brittle fracture.

Components that are exposed to very severe wear often also need to withstand bending and impact stresses, so toughness and resistance to brittle fracture are also important. Plain carbon steels and alloy steels containing carbide-forming alloying elements, e.g., chromium, molybdenum, and vanadium, are used (50 Mn 7, 42 Cr Mo 4), and also hypereutectoid steels such as the roller bearing steel 100 Cr 6. Tempering treatment is used to adapt the hardness and toughness to the application. In products made of steel plate, e.g., dumper trucks, garbage trucks, concrete mixers, chutes, and bunkers, weldability is important. Quenched and tempered struc-

Figure 300. Hardening the head of a rail
A) Isotherms after inductive heating (°C); B) Macrostructure after hardening with compressed air; C) Hardness distribution (HV10)

tural steels, e.g., Fe 690, have good wear resistance.

Austenitic manganese steel with 1.2 % carbon and 12 % manganese attains its very high wear resistance only after work hardening of the surface layer by impact wear loading. The toughness of the core structure is therefore suitable for dredger buckets, crusher jaws, and similar equipment. Steel castings are often used here.

Good wear resistance properties are also important in railway track [629]. This functions as support, roadway, and as guiding device, so that rails are subjected to very high dynamic stresses [630]. Where the wheel comes into contact with the rail, considerable deformation and work hardening of the steel of the rail takes place. The steel used for rails must have sufficient welding properties for welding processes used to produce continuous rails, e.g., flash-butt welding and aluminothermic welding. The steel grade UIC 90 A, specified by the Union International des Chemins de Fer (UIC) contains ca. 0.75 % C and ca. 1 % Mn, and is used by most railway companies. It must have tensile strength $> 880\,N/mm^2$ in the as-rolled condition.

In very highly stressed sections of railway line, wear resistance is increased by heat treating the head of the rail when this grade of steel is used (Fig. 300) [631]. A fine pearlitic structure is produced in the head area of the rail, giving increased hardness and tensile strength $\geq 1175\,N/mm^2$. This heat treatment is sometimes also carried out at the ends of the rails to improve resistance to impact stresses at the expansion gap in jointed rail.

For highly stressed sections of track in difficult terrain, steel rails with as-rolled strength > 1100 or even $1200\,N/mm^2$ are used [632], [633]. These steels have increased silicon content, with ca. 1 % Cr, and are alloyed with vanadium.

6.2.2.1.6. Steels for Pipelines

General. Gas, oil, water, chemical products, and solids, such as coal and ore in slurry form, are transported through pipelines. The choice of pipeline material depends on the operating conditions and the material being transported. On one hand, high operating pressures, and on the other, temperatures as low as $-60\,°C$ for gas pipelines in arctic regions, affect the choice of material. Corrosion damage is possible on the inside of the pipeline by the material being transported, and on the outside by the surrounding medium. Field welding processes must be suitable for these steels.

Properties and Testing. Testing of the material in the direction of the main stress is carried out on cylindrical tensile samples taken from the pipe wall in a transverse direction. To avoid the Bauschinger effect (see Section 6.1.2.1.2), the sample test pieces are taken in such a way that no dressing or straightening is required. Because of the high toughness requirements, a Battelle drop weight tear test (BDWT) is often carried out as well as the usual ISO V-notch test [634]. The sharply notched test pieces used to span the entire pipe wall thickness. The temperature at which a given proportion of the fracture is ductile (e.g., 85 %) is determined.

In gas pipelines, after initiation of a crack of a critical length, instable cracks can propagate at a high constant velocity over great distances. To avoid such crack propagation, the notched-bar

impact energy should be very high, and fracture should be fully ductile at the operating temperature. To determine the required toughness values, large-scale tests are carried out in which sections of pipelines of varrying toughness are tested in 200 m long test strings. A crack is initiated in a full-scale experimental pipeline which is kept under pressure. The crack propagation rate and mode of propagation give information about the behavior of the material [635]. With increasing pipe wall stresses, notched-bar impact energies must be higher to avoid long-running cracks (Fig. 301).

Figure 301. Required notched-bar impact energy as a function of hoop stress
Pipe diameter 1.420 mm; wall thickness 20 mm

The action of condensates containing hydrogen sulfide can lead to hydrogen-induced cracks starting at inclusions in the steel. Tests for resistance to this type of corrosion consist of keeping rectangular test pieces in a standard solution, saturated with H_2S, for 96 h, followed by metallographic inspection for the presence of hydrogen-induced cracks [636].

Whereas hydrogen-induced corrosion can take place at normal pressures, tensile stresses must be present for hydrogen-induced stress corrosion cracking to occur. This may be prevented by not exceeding a critical stress value which is in the region of 20 – 50 % of the yield strength of the material. Mechanical expansion or quenching and tempering of the tubes is also effective in reducing critical internal stresses [637].

Field weldability is of special significance when efficient welding processes are used, e.g., vertical down welding using cellulose-coated electrodes, and mechanized welding with protective gas, assessment of fabricability being the main consideration. For this purpose, a special carbon equivalent (CE) is calculated for these low-alloy steels [638]:

$$\begin{aligned}\mathrm{CE},\ \% = \mathrm{C},\ \% &+ \frac{\mathrm{Si},\ \%}{25} \\ &+ \frac{\mathrm{Mn},\ \% + \mathrm{Cu},\ \%}{20} \\ &+ \frac{\mathrm{Cr},\ \%}{10} + \frac{\mathrm{Ni},\ \%}{40} \\ &+ \frac{\mathrm{Mo},\ \%}{15} + \frac{\mathrm{V},\ \%}{10}\end{aligned}$$

This is suitable for assessing the hardening tendency of the steel. To measure susceptibility to cold cracking, the implant test is used.

Figure 302. Development of pipeline steels
Numerical values not shown on the abscissa, as measured toughness values depend on testing method
A = precipitation hardening; K = grain refining; P = reduction of pearlite content; D = dislocation hardening

Grades of Steel. In the development of steels for pipelines, steels with minimum yield strength 420 N/mm^2 were produced by microalloying normalized manganese steels with V and Nb. Good toughness properties were also obtained by a combination of grain refining and precipitation hardening.

The trend to higher material transport rates has led to increased pipeline diameters that are

Figure 303. Physical metallurgical processes during thermomechanical rolling as a function of the sum of deformation degrees, rolling time, and rolling temperature at various stages of rolling
SRT = slab reheating temperature

only possible with welded pipes and higher operating pressures. To minimize wall thickness and hence the mass of the pipeline, materials with higher yield strengths and higher toughness values were developed (Fig. 302).

Figure 304. Effect of C and Mn content on susceptibility to hydrogen-induced cracking
Solution: H_2S 2.5 g/L, pH 3

Steels with good field weldability and minimum yield strength 552 N/mm^2 were produced by thermomechanical treatment of low- carbon, low-alloy steels (Fig. 303) [639].

Further improvement in these properties can be obtained by quenching and tempering to a bainitic structure with an even smaller grain size than that in the thermomechanically produced structure. A combination of thermomechanical treatment with quenching directly from the final rolling temperature leads to particularly good results. For special applications, water-quenched and tempered pipes or heat-treated plates for the production of pipes are used.

Resistance to sour gas (hydrogen-induced cracking) is provided by extremely clean steels. The steel must be desulfurized to < 0.003 % S, and the residual sulfur must be reacted to form sulfides that do not easily deform into the shape of flat inclusions. This prevents formation of cracks by recombination of the hydrogen (dissolved in the structure in atomic form) to form molecules at these inclusions. Also, the formation of hard macrosegregations in the steel must

be prevented, as this too can promote the formation of hydrogen-induced cracks [640]. Reduction in carbon content can also reduce the segregation of other elements that contribute to hardening, e.g., manganese, and thereby reduce the tendency to hydrogen-induced cracking (Fig. 304).

Standards. A European standard for testing resistance to hydrogen-induced corrosion is in course of preparation. The German standard DIN 17 172 and the United States API standards 5 L, 5 LS, 5 LX, and 5 LU give specifications for pipeline steels. Customers' delivery conditions often give specifications that enable the demands of particular applications to be met, and correspond to the current state of technology.

6.2.2.2. Steels with Special Chemical Properties

6.2.2.2.1. Stainless Steels

General. Stainless steels have high resistance to chemically aggressive materials. They are used under normal environmental conditions (air, water), and in corrosive chemical solutions (acids, alkalis). These steels have chromium content $> 12\,\%$, and can also contain other alloying additions of Ni, Mo, Cu, Si, Ti, Nb, or other elements.

The areas of application of these steels range from domestic equipment, motor vehicles, and architecture, to chemical equipment, energy generation, marine technology, and environmental protection.

Properties and Testing. Steels with chromium content $> 12\,\%$ are passivated in the presence of oxygen or even such weak oxidizing agents as water. The surface becomes covered with a very thin, dense layer of oxide which restricts further electrochemical reactions and hence the dissolution of metal. Mechanical damage to the passive layer heals very rapidly. In water and many other aggressive media, only an extremely slight, uniform surface corrosion of the passivated surface takes place, which is virtually unmeasurable. Under reducing conditions, e.g., in sulfuric and phosphoric acids, a stable passive coating is not formed. Even very highly alloyed stainless steels dissolve smoothly and uniformly when in this active state. The temperature and concentration of the attacking medium therefore determine the rate of dissolution of a stainless steel. As this process takes place at a constant rate, the long-term behavior can be determined from short-term corrosion tests. Corrosion rates of 0.3 mm are tolerated in many applications. The release of metallic ions into the environment or the product is sometimes unacceptable, e.g., in pharmaceutical and photochemical products, food chemistry, or surgical implants.

Whereas component lifetime can be accurately estimated if surface corrosion is uniform, local corrosion phenomena can lead to sudden unforeseen failures. This group of local corrosion phenomena includes pitting, crevice corrosion, stress corrosion cracking, and intercrystalline corrosion.

Pitting of stainless steels is caused almost exclusively by chloride ions. These cause the steel to become locally active, and the active region is anodically dissolved. The resistance of stainless steels to pitting is improved by increasing the Cr, Mo, and N content (Fig. 305) [641]. The effectiveness of these elements can be expressed as the pitting resistance equivalent (PRE):

$$\mathrm{PRE} = \mathrm{Cr}\% + 3.3\,\mathrm{Mo}\% + 30\,\mathrm{N}\%$$

The incidence of pitting also depends on other factors, e.g., stability of the microstructure, condition of the surface, flow conditions in the attacking medium.

Figure 305. Correlation between pitting resistance equivalent (PRE) and the pitting resistance of stainless steels $FeCl_3$ test

Crevice corrosion is closely related to pitting. It is also caused by chloride ions, and is a modified form of pitting (Fig. 306). It can also occur in steels that are resistant to general pitting corrosion in the same attacking medium. Crevices between stainless steels and nonconductors, e.g., ceramic or plastic sealing materials, are especially damaging. Precautions should be taken against crevice corrosion at the design stage. The pitting tendency of stainless steel can be estimated by current density – potential determinations, which give a measure of pitting resistance. Estimation of resistance to crevice corrosion requires long-term tests of samples with a simulated crevice (contact with a plastic disk) in the attacking medium.

Figure 306. Correlation between PRE and resistance to crevice corrosion of stainless steels
$FeCl_3$ test

Stress corrosion cracking can cause components to fail completely within a very short time, by crack formation over the entire load-bearing section. The condition which leads to stress corrosion cracking is attack by an aggressive medium combined with mechanical tensile stress. Media which attack austenitic stainless steels include chloride- containing and alkaline solutions. In chloride- containing solutions, stress corrosion cracking often starts at previously formed pits. Alloying elements that improve pitting resistance also improve resistance to stress corrosion cracking in chloride solutions. Chloride-induced stress corrosion cracking can be almost completely controlled by high nickel content. The critical mechanical stress for this type of corrosion is very low ($50\,N/mm^2$) [642], [643], as is the temperature above which stress corrosion cracking can take place in aqueous chloride solutions (ca. 50 °C; Fig. 307) [644]. Testing for susceptibility to stress corrosion cracking is performed on mechanically stressed bend or tensile test pieces simultaneously subjected to the attack of the medium, whose composition and temperature must be kept constant for the duration of the test.

Figure 307. Effect of temperature and chloride concentration in the aqueous phase on the stress cracking resistance corrosion of U-bend specimens of 18 Cr 10 Ni steel in NaCl solutions
Isothermal storage of specimens with three-phase interface-Circles = stress crack corrosion, starting from pitting sites; diamonds = no stress crack corrosion after a test period of 1000 h

In chromium- containing steels, chromium-rich carbides $Cr_{23}C_6$ are precipitated at the grain boundaries at moderate temperatures. This causes the zone adjacent to the grain boundaries to be depleted in chromium (Fig. 308) [645]. The steel then becomes sensitized to intercrystalline corrosion. This can take place, e.g., by stress-relief heat treatment of the entire component, or in areas close to a weld. This selective corrosion takes place only in the presence of an attacking medium. It can be prevented by greatly reducing the carbon content, i.e., to $< 0.07\,\%$ or even $< 0.03\,\%$, or by bonding the carbon with Nb or Ti to form stable carbides. To determine resistance to intercrystalline corrosion, samples of the material are metallographically examined for grain boundary separation after a predetermined sensitization treatment, e.g., 30 min at 650 °C, followed by prolonged exposure to a test solution. Solutions of $CuSO_4/H_2SO_4$ or HNO_3/HF are used for these tests. The most sensitive is the Huey test in boiling HNO_3, as this is sensitive not only to chromium depletion, but also to the precipitation of nitrides and intermetallic

phases [646]. Some types of selective corrosion that seldom occur with stainless steels include "knife-line" attack (near weld seams on stabilized steels) and corrosion fatigue [647].

Figure 308. Chromium depletion near the grain boundary caused by precipitation of Cr-rich carbides at the grain boundary

Grades of Steel. The first classification of stainless steels by structure [648] was made in 1920, and is used today in all systematic descriptions. One of the most well known is classification by the Schaeffler diagram [649], which describes the microstructures of weld materials of chromium and Cr – Ni steels (Fig. 309).

Figure 309. Effect of alloying elements on the microstructure

Ferritic Steels [650]. This group starts with 11 % Cr steels with low corrosion resistance, e.g., for vehicle construction and for containers. Further steels contain ferrite, together with larger amounts of transformation structures. Steels for motor vehicle catalytic exhaust systems contain 12 – 18 % Cr. Dishwashers and washing machine drums contain 18 % Cr. The corrosion resistance of this grade of steel can be further improved by the addition of 2 % Mo. Further improvements have led to a 30 % Cr, 5 % Mo steel. These superferrites are produced with extremely low carbon and nitrogen content, and can be further stabilized by addition of Nb. Because of their very high PRE, they can be used when very good pitting resistance properties are specified. Stabilization, i.e., bonding of all the carbon and nitrogen by Ti or Nb, is essential for all components of ferritic steels intended for welding, to prevent intercrystalline corrosion in the heat-affected zone.

Normal ferritic chromium steels have their ductile – brittle transition temperature near room temperature. As they do not undergo transformation, when they are hot rolled in large sections there is a tendency to form a coarse-grained structure which leads to a further reduction in toughness. In the superferrites, reduction of the carbon and nitrogen content causes the transition temperature to be shifted to lower temperature, and the upper shelf energy measured on the notched-bar impact specimen to be significantly improved. With increasing Cr and Mo content, 475 °C embrittlement causes the embrittlement tendency of ferritic chromium steels to increase in the range 350 – 500 °C, and precipitation of χ- and σ-phases [651] causes a similar increase in the 500 – 800 °C range. This means that these steels are not suitable for prolonged use > 300 °C, and that cooling from the final working temperature must be very rapid through this temperature range. With high Cr and Mo content, the required cooling rate can be achieved only with small sections. A superferrite containing 28 % Cr and 2 % Mo, with sheet thicknesses ≤ 15 mm, can be successfully worked [652]. This steel is used for seawater desalination plants and flue gas desulfurization plants.

Martensitic Steels. Only moderate corrosion resistance can be achieved with martensitic chromium steels because customers require chromium content 13 – 17 %, but it can be somewhat improved by adding ca. 1.5 % Mo. Higher strength and hardness can be achieved with normal martensitic chromium steels with carbon content 0.20 – 1 %.

In the quenched and tempered condition, steel grades containing 0.20 % C are used for steam turbine blades and other machine components. The higher-carbon steels are used in the hardened condition for cutting equipment, roller bearings, and components with good wear resistance properties. The toughness can be increased by stress relieving at 200 – 350 °C.

An alternative to the quenched and tempered chromium steels with 0.20 % C is provided by the nickel-containing martensitic steels in which the carbon content has been reduced to < 0.05 %, and ≤ 6 % Ni is added as the austenite former. These measures lead to considerable improvements in toughness, corrosion resistance, and welding properties.

Another group of steels with even higher strength properties has been developed from these nickel-containing martensitic steels. The addition of Al, Cu, Nb, or Ti causes precipitation hardening, i.e., intermetallic phases, leading to strengths of up to 1400 N/mm^2 in these maraging steels.

The nickel-containing martensitic and maraging steels should not be used above 300 °C, owing to the possibility of structural changes.

Austenitic Steels. The austenitic Cr – Ni steels constitute the highest proportion of stainless steels produced. As well as the basic grade containing 18 % Cr and 9 % Ni, a large number of steels with reduced carbon content and additions of N, Mo, Cu, Si, Ti, and Nb have been developed.

The Cr – Ni steels are used for kitchen equipment, interior decorations, and components of exterior architecture that are not subjected to severe corrosion. Austenitic Cr – Ni – Mo steels are preferred for greater resistance to pitting and crevice corrosion by aggressive outside atmospheres, for domestic pipework, and in automobile construction. Both these basic types of austenitic steels are widely used in the chemical industry.

Austenitic steels with high proportions of alloying elements have been developed to improve their general corrosion resistance and to prevent selective corrosion.

To prevent intercrystalline corrosion, almost all austenitic grades of steel produced today have reduced carbon content and/or are stabilized with Ti or Nb/Ta. Pitting and crevice corrosion resistance are improved by increasing the Cr, Mo, and N contents (Figs. 305 and 306). Chromium content ≤ 30 % and molybdenum content ≤ 6 % are typical of state-of-the-art austenitic steels with good resistance to chloride-containing media, sulfuric acid, and organic acids. A Cr – Ni steel with added Si is particularly resistant to concentrated nitric acid.

As the austenitic Cr – Ni steels have low yield strength (0.2 % offset value ca. 200 N/mm^2), relatively large sections are needed for high mechanical loads. This situation can be improved by the addition of nitrogen, which causes a very large increase in the yield strength of austenitic Cr – Ni steels (Fig. 310) [653]. Melting or electroslag remelting under pressure gives considerably higher nitrogen content than can be achieved by melting under atmospheric pressure, i.e., maximum 0.4 % N. Nitrogen improves both the yield strength and the austenite stability. Precipitation of carbides and intermetallic compounds such as χ-, σ-, and Laves-phases is shifted to longer annealing times by nitrogen, so that the working of Cr- and Mo-containing steels is facilitated. Under long-term exposure at high temperature embrittlement must be guarded against. Sensitization to intercrystalline corrosion by prolonged operation at high temperature must be borne in mind if periods of operation under wet corrosion conditions are expected.

Figure 310. Effect of nitrogen content on the 0.2 % offset yield strength $R_{p0.2}$ of nitrogen-alloyed austenitic steels at room temperature

When welding austenitic steels with high Mo content, segregation and precipitation in the weld and heat-affected zone can take place, with

a reduction in corrosion resistance. This effect becomes more significant at higher Mo content (Fig. 311) [641], [654]. If part of the Mo is replaced by Cr and N, the welded joint has a slightly reduced corrosion resistance for the same PRE.

Figure 311. Critical pitting temperature of stainless steels in the solution-annealed condition and after autogenous gas tungsten arc welding (GTAW) without filler

Ferritic – Austenitic Steels. The importance of the ferritic – austenitic steels has increased considerably because of their spectrum of useful properties [655]. Their composition range, i.e., $>20\,\%$ Cr, $5-8\,\%$ Ni, and $\leq 3\,\%$ Mo, leads to a mixed structure of austenite and ferrite. This enables 0.2 % offset yield strength $>450\,\mathrm{N/mm^2}$ to be achieved at room temperature.

The higher PRE compared with standard austenitic steels gives this type of steel a considerably better resistance to chloride-induced selective corrosion. Their general corrosion resistance is maximized by adhering to certain ratios of austenite to ferrite, so the achievement of this structural state is mainly determined by the ratio of ferrite formers to austenite formers (Fig. 309). These steels also have added nitrogen. This has an austenite-forming action, increases the PRE, and decreases the precipitation of σ-phases that lead to embrittlement. When specifying possible operating temperatures, the possibility of 475 °C embrittlement must also be borne in mind. This limits the highest operating temperature to 280 °C.

The composition of the welding material must be such that the cooling process after welding gives a ferrite/austenite ratio corresponding to that of the base material.

The ferritic – austenitic steels have a lower thermal expansion and a better thermal conductivity than the austenitic steels.

The ferritic – austenitic grades of steel are used in seawater desalination plants, sour gas pipelines, and especially where their good resistance to stress corrosion cracking and corrosion fatigue is important, e.g., in chemical and petrochemical industries, especially if the components concerned are in motion.

Standards. A list of standard grades of stainless steel is planned for the European standards. The Europea standards EN 10 028-5 specify stainless steels for plate and strip for pressure vessels; EN 10 088-1 gives delivery requirements for plate and strip for general use; EN 10 088-2 for rod material for general use; EN 10 088-3 for flat products for pressure vessels; EN 10 222-5 for forgings; and EN 10 213-4 for steel castings. Standards for stainless steel tubes are also planned.

The following specifications for stainless steels are given in United States standards; for sheets, ASTM A 167, A 176, A 240; for seamless tubes, ASTM A 213, A 268, A 269, A 270, A 271, A 312, A 336, A 511; for welded tubes, ASTM A 249, A 268, A 269, A 270, A 312, A 409; for forgings, ASTM A 403.

6.2.2.2.2. Heat-Resistant Steels

General. Heat-resistant steels have good resistance to high-temperature corrosion, especially by hot gases, ash constituents, and molten salts and metals at temperatures $>550\,°\mathrm{C}$. As well as chemical resistance, these steels must also have the necessary mechanical load-bearing properties at high temperature, and must be unaffected by temperature changes. For prolonged use at high temperature, the microstructure must remain stable, and embrittlement should not occur.

Properties and Testing. The rate of scale formation (oxidation rate) on plain carbon steel increases with temperature. This rate can be significantly reduced by alloying with Cr, Al, and Si. The oxidation products of these elements form protective layers which restrict oxidation processes at the metal surface. Resistance to scaling increases with increasing proportions of

the elements that form protective layers. Small additions of Ce, Hf, or Y increase adhesion of the oxide layer to the metal surface.

The scaling resistance of a steel is measured by gravimetric determination of the weight loss due to scaling of test pieces after long periods at high temperature. Adhesion of the oxide layer can be assessed by cooling the samples a number of times during the test (Fig. 312). Components made of these types of steel are usually used not only in air, but also in atmospheres with other partial pressures of oxygen, possibly also containing reactive gaseous, solid, or liquid components. Testing should be carried out in these atmospheres in such cases.

Figure 312. Mass changes on thermal cycling
Solid lines = Fe – Ni – Cr steel + Ce; dashed lines = Fe – Ni – Cr steels + Si

The tests can simulate actual operating conditions. For example, alloys for heating elements are very rapidly heated to the testing temperature by an electric current, and are then subjected to many more temperature changes. The mechanical stresses thus applied to the scale resemble those in a real situation.

As well as hot corrosion tests, high-temperature long-term testing is also carried out in order to obtain mechanical parameters for design purposes. These tests are sometimes carried out in aggressive gas mixtures, with very sophisticated equipment. Toughness tests are also carried out after long-term exposure to high temperatures to determine the embrittlement tendency of these steels. The ferritic chromium steels containing $> 13\,\%$ Cr tend to undergo 475 °C embrittlement within the range 300 –550 °C [656], and σ-phase embrittlement in the range 600 – 800 °C [657]. At higher operating temperature, existing precipitates redissolve, reversing the effects of embrittlement. In many cases, embrittlement does not affect operating behavior, as shown by experiments on valve steels [658]. However, embrittlement caused by service exposure of components must be taken into consideration when making repairs.

For valve steels, determination of fatigue limits at high temperature and an engine test for the qualification are important.

Ferritic Steels. If the specifications for mechanical load-bearing capacity are not too high, high-temperature corrosion resistance can often be obtained by the use of ferritic chromium steels. These contain 12 – 25 % Cr with additions of Al and Si. As they do not contain nickel, these steels are stable in neutral and oxidizing atmospheres, even if these have sulfur-containing components. However, they are significantly less resistant to reducing H_2S-containing atmospheres [659], [660]. If reducing gases such as CO or hydrocarbons are present, carburization of ferritic steels can occur at operating temperatures $> 500\,°C$. This carbon can then combine with a significant portion of the active chromium content, leading to a considerable decrease in scaling resistance. In gases rich in nitrogen or ammonia, scaling resistance can be reduced by combination of the nitrogen with the active Al to form AlN, especially if there is damage to the scale layer.

Whereas the usual heat-resistant chromium steels, which contain additions of $\leq 2\,\%$ Si and Al, form a protective layer consisting mainly of chromium spinels at high temperatures, chromium steels with aluminum content $> 4\,\%$ form a dense protective layer of Al_2O_3 which gives them even better scaling resistance. As these steels have high electrical resistance, they are especially suitable for use in heating elements. The low variation in electrical resistivity with temperature of these steels is also an advantage when they are used as high-temperature conductors. The higher aluminum content also improves their resistance to sulfur-containing gases and suppresses precipitation of the σ-phase, a cause of embrittlement (Fig. 313) [657]. In these steels, an Al content of 6 % should not be exceeded at 15 – 25 % Cr to prevent the formation of a coarse-grained structure.

Figure 313. Effect of silicon and aluminum on the time for onset of σ-phase formation at 600 °C in steels containing ca. 24 % and ca. 30 % Cr

Steels used in the valves of internal combustion engines, which operate at ca. 550 °C, should have high hot strength and good hot corrosion resistance. They are therefore quenched and tempered steels with chromium content 9 – 18 %, and also sometimes contain higher levels of Si and additions of the special carbide formers Mo, W, and V to improve hot strength and hot wear resistance properties. These steels are oil quenched and tempered to a strength of 900 – 1100 N/mm^2. Their structure consists of tempered martensite with included carbides.

Austenitic Steels. If higher mechanical stresses are to be expected, heat-resistant austenitic Cr – Ni steels, Ni – Cr alloys, or Co – Cr – Fe alloys are used. These steels, too, mainly rely on chromium to give oxidation resistance, chromium content being 18 – 27 %. Silicon, another ferrite former, can be added at $\leq$ 2.5 %. To maintain a fully austenitic structure with this high level of ferrite formers, nickel content is 10 –36 %. This prevents the formation of δ-ferrite, which under exposure to high temperature would accelerate the precipitation of the σ-phase, which causes brittleness. The austenitic steels have a lower tendency to embrittlement then the ferritic steels, and steels with > 30 % Ni are in any case not likely to be affected by σ-phase precipitation.

Unlike ferritic steels at room temperature, austenitic steels have very good toughness properties and good deformability. Their resistance to carburizing and nitriding atmospheres is also significantly better. Steels containing > 30 % Ni or > 2 % Si are particularly stable in carburizing gases (Fig. 314) [661]. A layer of SiO_2 forms under the chromium spinel protective layer, directly in contact with the metallic surface. This strongly inhibits carburization. Nickel – chromium alloys have the highest resistance to carburization and nitridation [662]. The diffusion and solubility of carbon and nitrogen decrease with increasing nickel content.

Figure 314. Carburization at 950 °C after 500 h in H_2 10 L/h + town gas 10 L/h
Carbon analysis values at various depths

If the heat-resistant steels contain small amounts of elements that are more easily oxidized than chromium, e.g., Al, Ti, or Si, internal oxidation of these elements can take place under the interface between the scale and the steel [663]. The effectiveness of these elements for improving scaling resistance or hot strength is reduced, and the load-bearing section is weakened.

If the content of these elements is so increased that a dense continuous layer of the oxide is formed, the solubility of the oxygen that diffuses into the metallic material is limited by its equilibrium concentration in the oxide layer. Because of the decrease in the concentration of oxygen from the interface region to the interior of the material, internal oxidation can take place only of those elements that are more easily oxidized than the scale-forming elements. The formation of a pro-

tective scale requires the presence of > 4 % Al or > 2 % Si.

Attack by reducing sulfur-containing gases can cause damage by internal sulfidation in these high-nickel steels, as shown in the Pourbaix – Ellingham diagram (Fig. 315) [664]. Liquid nickel sulfide is formed at > 650 °C in and under the oxide layer, which loses its protective action.

Figure 315. Stability diagram for some alloying elements and the service conditions for high- and low-sulfur coke

Chromium – nickel steels containing > 30 % Ni and 20 % Cr, and nickel alloys containing 20 % Cr are used as austenitic electrical resistance alloys. Their resistance is lower than that of ferritic electrical resistance alloys. Their higher hot strength can be an advantage for various applications in this area. However, they cannot be used at the high temperatures of the ferritic electrical resistance steels, as their scaling resistance temperature does not exceed 1200 °C.

Because of their high hot strength, austenitic valve steels are used at material temperatures of 900 °C. This means that they can be exposed to the severe conditions under which exhaust valves operate. Here, they are subjected to the strongly corrosive effects of the products of the combustion of the fuel and its additives [658]. The products of the oxidation of the organic sulfur and vanadium compounds in diesel fuel also contribute to the corrosive attack on exhaust valves. The liquid combustion residues in particular reduce the scaling resistance, while the solids can cause wear of the valve faces. The latter are often provided with cladding to improve the lifetime of the valves. Austenitic valve steels contain 0.60 % C and 0.45 % N to increase the hot strength. As well as the 20 % chromium, Mo, V, and W are added as special carbide and nitride formers. Manganese content ≤ 10 % and nickel content ≤ 20 % ensure that an austenitic microstructure is formed. Precipitation hardening, which also takes place during operation of the valve in the engine, leads to the required strength properties, including fatigue resistance, at the high operating temperatures.

Standards. The German Stahl-Eisen-Werkstoffblatt 470 gives specifications for heat-resistant steels. Electrical resistance alloys are described in DIN 17 470, and valve materials in DIN 17 480.

6.2.2.2.3. Steels for Hydrogen Service at Elevated Temperatures and Pressures

General. In high-pressure syntheses, oil refining, and other high-pressure technologies, hydrogen at high pressure and temperature can have an effect on constructional material. These materials must be resistant to attack by H_2 under the operating conditions, and must have sufficient hot strength to be stable under the high mechanical loads.

Properties and Testing. At metallic surfaces, H_2 molecules at high pressure can be split up into H atoms which can then penetrate into the metallic lattice. At > 200 °C, this atomic hydrogen can react with Fe_3C in the steel structure to form CH_4. The steel is thus decarburized where the reaction occurs and consequently loses its strength. The CH_4 formed cannot diffuse through the metallic lattice, and collects at the grain boundaries and inclusions. There, the CH_4 and the recombined H_2 molecules give rise to high pressures which can destroy the material by crack formation [665]. Remedial measures can be taken by bonding the C to form stable carbides, e.g., with the alloying elements Cr, Mo, V, W, Ti, Nb, and Zr. With increasing levels of these elements, i.e., with decreasing Fe content of the mixed carbides formed, the temperature range within which the steels are stable to the high-

Figure 316. Limiting conditions for the stability of steels in high-pressure hydrogen (Nelson diagram)

pressure hydrogen is shifted upward. The critical temperature for the various steels has been determined by comprehensive and very costly autoclave experiments with H_2 [666]. A summary of operating experience of several decades was first produced by Nelson [667] in the form of a resistance diagram (Fig. 316), which is continually updated, and gives information for choosing suitable materials for known operating temperatures and hydrogen partial pressures [668]. The continuous lines in the diagram show the limit of resistance for the various steel compositions, i.e., for which higher temperatures or pressures would lead to internal damage by the high-pressure hydrogen. For the dashed lines, internal damage does not occur, though the use of these steels is limited by surface decarburization.

As with high-temperature steels, the hydrogen-resistant steels are also tested at high temperature by hot tensile measurements and by creep tests to establish the data used in design calculations. The scaling resistance in air or sulfur- containing gases, depending on the application, can also be important in the choice of steel.

Grades of Steel. With wall temperatures 200 – 400 °C, steels containing 0.5 – 1 % Mo and < 3.3 % Cr are used in hydrogenation plants. For resistance to higher hydrogen pressures, steels containing 5 – 9 % Cr and 0.5 – 1 % Mo are available, these being mainly used in oil refineries. If high values of creep rupture strength are required in the range 550 – 600 °C, 12 % Cr steel containing Mo and V, a material commonly used in the construction of power stations, can be used. Steels with higher chromium content also have better resistance to corrosion by sulfur-containing substances.

If the hydrogen contains N_2 and NH_3, as in the high-pressure synthesis of ammonia, nitridation of the steel at > 400 °C is likely. This produces hard, brittle nitride layers on the surface, and these readily spall off, reducing the cross section of the component. Ferritic steels cannot be used under the conditions of methanol synthesis, as the CO in the gas forms carbonyls at 120 – 300 °C, leading to the removal of material; the steel must be clad with austenitic Cr – Ni steel or copper to minimize material loss.

Heat treatment of these steels should ensure the precipitation of stable carbides to optimize stability to high-pressure hydrogen, i.e., high tempering temperatures and long soaking times. High strengths should be avoided. These procedures should also be used when heat treating welded components. Formerly, austenitic welds without subsequent heat treatment led to massive hydrogen damage in the weld-affected zones. Rapid cooling of the hot weld caused the formation of unstable higher Fe- containing carbides. This kind of damage does not occur if the weld material is identical to the material of construction, enabling subsequent heat treatment to be carried out. The best high-pressure hydrogen resistance is secured if the welded component is re-heat-treated.

Components made from these grades of steel are often very thick-walled, as operating pressures are very high (up to 100 MPa), so it is important to achieve uniform through-hardening

with a uniform microstructure and a high degree of purity. This maximizes resistance to hydrogen embrittlement.

Austenitic Cr – Ni steels have very high resistance to hydrogen embrittlement because of their high chromium content and the possible presence of other carbide-forming alloying elements, e.g., Mo, V, Ti, and Nb. They also have good corrosion resistance to other materials in the reaction gas, such as H_2S at 650 °C. In NH_3-containing gases, a thin, dense nitride protective layer is formed on austenitic Cr – Ni steels [669].

Standards. Specifications for steels resistant to hydrogen embrittlement are given in the German Stahl-Eisen-Werkstoffblatt 590, and for cast steel resistant to hydrogen embrittelement in Stahl-Eisen-Werkstoffblatt 595.

United States standards inlcude: ASTM A 200 for seamless tubes of medium-alloy steels for refineries; ASTM A 213 for seamless tubes of ferritic and austenitic steels; ASTM A 335 for seamless tubes of ferritic steels for high-temperature use; and ASTM A 336 for forgings of ferritic and austenitic steels for pressure vessels.

6.2.2.3. Steels with Special Physical Properties

In steels that have been developed simply so that certain physical properties can be utilized, mechanical properties are frequently unimportant. This does not apply to any other classes of steel. The soft magnetic steels are by far the most important members of this special group, not only from the tonnage aspect. Nonmagnetizable steels and steels with good electrical conductivity also play an important part in the economy. In steels with defined thermal expansion and special elasticity characteristics, the iron content is only ca. 50 %, exceptionally reaching 70 or 80 % [670]. In permanent magnets, the iron content is important, but most of these materials are not strictly steel products [671].

The highly developed techniques for measuring all the important physical properties cannot be treated within the scope of this article.

6.2.2.3.1. Soft Magnetic Steels [672]

(→ Magnetic Materials, Chap. 5.1.)

General. Traditionally, all materials that have coercivities of less than 1000 A/m are classified as soft magnetic. The International Electrical Commission (IEC) has proposed the following classification of soft magnetic materials:

A	pure iron
B	low- carbon steel
C	silicon steel
D	other steels
E	nickel – iron alloy
F	cobalt – iron alloy
G	other alloys
H	soft magnetic ceramics

Materials B – D are described below.

Low-Carbon Steel/Soft Iron. The term soft iron describes steels produced economically in normal steel production processes, containing a minimum of impurities, and only small additions of certain elements. Soft iron is produced in almost all product shapes for applications which require the production, amplification, or shielding of constant magnetic fields.

The various applications of soft iron require the following properties: ease of magnetization to high values, high saturation polarization, high maximum permeability, and low coercivity. The magnetic properties must change only insignificantly in the course of the working life of the component. If low core (power) losses are also required, the eddy currents associated with the good electrical conductivity must be taken into account.

For good soft magnetic properties, it is important that the iron should have an undisturbed ferritic microstructure and a large grain size. Precipitates caused by carbon or nitrogen and inclusions caused by oxygen and sulfur disturb the microstructure. Levels of these elements must therefore be minimized. The size of the precipitated particles becomes important if their diameter is comparable with the diameter of a Bloch wall (Fig. 317) [673]. The chemical bonding of the oxygen (deoxidation), sulfur, and nitrogen is carried out by adding small amounts of manganese and aluminum, which do not harm the magnetic properties. It is especially important to react any residual nitrogen with aluminum to prevent magnetic aging. As the grain size also

has a great influence on the coercivity (Fig. 318) [674], steps must be taken during further processing and heat treatment to produce a coarse grain.

Figure 317. Coercivity as a function of average diameter of the precipitates in iron with 0.02 % C at constant volume fraction of the precipitates [673]

Figure 318. Coercivity as a function of average surface area of the grains for "pure" iron with 0.02 % C and 0.07 % Si [674]

An important application for soft iron is in the production of a wide variety of relays. Cold- or hot-rolled strip, merchant bar, wire, forgings, and castings can be used for this purpose. Heavy forgings, e.g., for accelerator magnets (up to 100 t) in large-scale research installations, are also produced in soft iron.

Electric Sheets. Electric sheets are mostly thinner than 0.65 mm, and are unalloyed or contain up to 4 % silicon. They are used in the construction of magnetic cores consisting of fine laminations in electrical equipment, e.g., motors, generators, transformers.

Electric sheets are produced almost entirely as cold-rolled strip manufactured on a large scale, and are usually coated on one or both sides with a thin layer of insulating material. Electric sheets must be easily magnetizable, and must have a low power loss on cyclic magnetization. Other requirements for further processing include good punching properties, a high specification for flatness, and a narrow thickness tolerance.

For small machines, unalloyed steel with low polarization is often sufficient, as the power losses and heat generation due to eddy currents in the core do not cause problems. At higher powers, the problems intensify, and the power loss becomes very important. Increasing silicon content increases electrical resistance and decreases power loss. Another approach to the problem is to reduce the thickness of the sheet.

The economic pressure for reduction in power losses led, in the 1940s, to the industrial production of the so- called Goss texture (cube on edge texture) [675], in cold-rolled electric sheets. In the Goss texture, the crystals in the microstructure are oriented such that the more easily magnetizable edge of the cube ⟨100⟩ is in the rolling direction, and the normal to the rolling direction in the plane of the sheet coincides with a face diagonal ⟨110⟩ of the cubic unit cell (Fig. 319) [676].

Figure 319. Positions of unit cubes in the crystal structure [676]
A) Goss texture; B) Cube texture

This development of the first grain-oriented electric sheet, with thickness 0.35 mm, resulted in greatly reduced power losses in transformers [677]. In rotary machines, this type of sheet is of limited application, and nonoriented electric sheets are nearly always used.

The silicon content is limited to ca. 3.5 % for the benefit of the cold rollability. In nonoriented electric sheets, an aluminum content of a few tenths of a percent completes the effect of the silicon. In grain-oriented electric sheets, this effect cannot be utilized, as the conditions for producing the texture require very close control of the chemical composition of the steel with respect to all elements.

Figure 320. Relationship between specific power loss and sheet thickness [679]
RGO = regular grain oriented; HGO = high permeability grain oriented

Attempts to develop grain-oriented electric sheets with cube texture did not led to satisfactory and economically justifiable results. Further developments of regular grain oriented (RGO) electric sheet with Goss texture in the last 20 years have led to major improvements in the energy efficiency of power transformers. A first step was reduction of the sheet thickness to 0.30 mm and later to 0.27 mm. The next step was the development of high permability grain-oriented (HGO) silicon steel by changing the chemical composition of the steel to improve the degree of orientation and by using an insulating coating (see Fig. 320) [678], [679]. Further decreases in transformer power losses have been achieved by laser treatment of the sheet surface to refine the domains [680], and a further reduction of the sheet thickness to 0.23 mm. However the costs of the surface treatment and of producing the 0.23-mm product are high. Further developments on nonoriented and on grain-oriented electric steel sheet promise further energy savings.

6.2.2.3.2. Other Steels with Special Physical Properties

Steels with soft magnetic properties are also required to operate in situations where mechanical stresses are also present, e.g., generator shafts or steel sheet in laminated pole pieces. The properties of these steels, which depend on their chemical composition and microstructure, represent a compromise between opposing requirements.

Nonmagnetizable Steels [681]. These have a stable austenitic structure, i.e., there must be no $\gamma - \alpha$ transformation or martensite formation, even at low temperatures or after cold forming [682]. These steels are used to prevent harmful interactions with the magnetic field of the environment, e.g., in inductor cover rings on generator shafts, in the structures of ships in the vicinity of the compass, in equipment for low-temperature physics research, and in many other areas. These steels are often required to have good mechanical and anticorrosion properties.

The addition of a high proportion of manganese (ca. 18 %) is the simplest method, if the steel is not to be used appreciably below room temperature [683]. However, in most cases, high-alloy chromium and Cr – Ni steels are necessary. These often contain added nitrogen (ca. 0.5 %) to ensure that specifications are met.

Steels with Good Electrical Conductivity [684]. These are required for the conductor rails of electric railways, for telephone and telegraph wires, and for other current-carrying applications in high- and low-current technology. They are used for reasons of strength and sometimes cost in preference to materials with higher conductivity, e.g., copper and aluminum.

It is important to maintain low levels of impurity elements, including carbon and silicon

[685]. This must be borne in mind when selecting the raw materials to be used in steel production.

6.2.2.4. Steels with Special Processing Properties

When choosing a material for the manufacture of a particular component, the properties of the material that are important for the use of the component, the price, and the costs for manufacturing the finished component from this material are decisive. Most of the properties of steel as a construction material, and the extent to which it is possible to match these to the requirements, have been described in detail in previous sections. In the following section, groups of steel grades are described for which the mechanical properties are not the only properties of prime importance. They have been extensively developed to facilitate the manufacture of components by cold forming or machining, and to make these processes more convenient and cost effective.

6.2.2.4.1. Steels for Flat Products for Cold Forming [686]

General. Thin flat products, up to ca. 16 mm thick, especially suitable for cold forming, represent by far the greatest proportion of rolled steel products. These are mainly manufactured in the form of hot- or cold-rolled strip, with or without metallic or organic coatings (see Section 6.2.1 and EN 10 079), but also to a small extent as plate. Improvements in the grades of steel with good cold forming properties in these product shapes have led to great improvements in design, production, and manufacturing costs, especially in vehicle construction. These developments include not only mild steels, but also steels with tensile strength of up to 600 N/mm^2, the latter being associated with developments in forming techniques and die design (Fig. 321) [687]. In the interests of the style and safety of the autobody, complicated shapes can be produced from steel sheets without problems. Weight savings can be achieved by using high-strength grades of steel sheet with good formability [688]. Cold-formed parts made from thin flat products, welded to components have replaced forgings, e.g., for suspension systems, and in commercial vehicle construction.

Figure 321. Factors influencing the result of a forming process

Corrosion problems in the automotive industry have practically been eliminated by galvanized steel sheet with good cold formability, following the development of suitable painting and welding processes for these sheets [689].

The cold forming properties of steel depend on its microstructure. However, the cold forming of flat products is very different from cold extrusion and cold heading of massive products. In bending and folding operations yielding of the material is easy to control; tearing must be avoided. In deep drawing and stretch forming stress conditions are considerably more complex. Actual stampings usually exhibit a combination of deep drawing and stretch forming.

Properties and Their Measurement. For deep drawing steel sheet, the most important properties for quality control are those determined from tensile tests, i.e., yield strength, tensile strength, and percentage elongation after fracture. In contrast to all other steel groups, the maximum allowable values of yield strength and tensile strength are important in this case. Whether minimum values should be quoted in the specification, as a basis for calculation by the designer, is in dispute, because cold form-

ing leads to considerable work hardening in the finished stamping.

In the last 20 years, two parameters have become of increasing interest, both determined by tensile tests: the normal anisotropic or plastic strain ratio (r value) and the work hardening exponent (n value) [690], [691]. The r value is the ratio of the change in width to the change in thickness of a tensile test specimen deformed by stretching, and is an expression of the relative tendency of the metal to yield in the width direction ($r \gg 1$) or in the thickness direction ($r<1$) [692]. If during deep drawing, the material becomes thinner, the load-bearing cross section is reduced, and the drawing stress that can be applied without tearing is limited. The r values for deep drawing should be as high as possible.

Different r values in the sheet plane at various angles to the rolling direction (i.e., the planar anisotropy Δr) are responsible for the occurrence of "earing" during pure deep drawing. The best conditions for avoiding this are provided when $\Delta r \approx 0$. The anisotropic properties of the steel sheet are a result of the hot rolling conditions and the annealing practice of the cold-rolled strip, producing the desired texture in the microstructure.

The work hardening exponent (n value) is determined from the true stress – true strain curve, and is given by the slope of this curve in log – log coordinates. The n value indicates the degree to which the material can withstand a higher stress after a given deformation than was possible in the starting condition. This work hardening of the deformation zone during stretch forming has the effect that the adjacent zone of even lower strength is included in the stretching process and necking is avoided. The r and n values are useful for the further development of steel grades, and can also be an aid in deformation analysis of difficult new deep-drawn items, using the grid measuring technique [693].

Tests that simulate forming operations, e.g., the cupping test for deep drawing or the bulge test for stretch forming, are now of little importance [694], but procedures such as the bending or double folding test (handkerchief test) are widely used for on-line monitoring. The adhesion and formability of corrosion-resistant coatings are tested by the ball impact test, or by forming profiles with various degrees of edge sharpness (lock forming test).

The surface condition of the steel sheet (produced by hot rolling, cold rolling, or surface coating) and the surface finish (smooth, matt, or rough) are of great importance for the forming process. To meet the customer's requirements, the cold-rolled sheet can be given a defined surface roughness, which is measured by contact stylus instruments.

Steel Grades and Product Shapes. The cold formability of flat products depends on the microstructure, which is determined by the chemi-cal composition, the rolling technique, and the heat treatment. A discussion of steel grades must therefore be linked with the shape of the product. The most important steel product used is coldrolled sheet, with or without coatings. Today, this is only produced from hot-rolled wide strip, nearly all produced from continuously cast material. With very few exceptions, only fully killed steel (by Al) is used. Up to 20 years ago, rimming steel was widely used in sheet production, as a defect-free surface and a higher yield was more easily achieved with this steel type at ingot casting (see Section 3.5.2). Rimming steel is still used if there is a shortage of strand casting capacity.

Unalloyed mild steels, with carbon content < 0.1 %, have the best cold formability as cold-rolled sheet. The specifications in EN 10 130 describe a series of five sheet grades with graded cold formability, improving as the tolerances in chemical composition are tightened and the specifications of the properties are increased. The fifth grade (Fe P 06), which has the highest cold formability, is a so-called IF steel (interstitial-free), with a very low carbon content (<0.02 %), in which the carbon and nitrogen are all combined with Al and Ti (or Nb) [692]. This steel sheet grade shows no yield point elongation in the stress strain curve after annealing. With the other sheet grades, the yield point elongation is removed by a final skin pass rolling (temper pass), to prevent the formation of Lüders lines in the surface after cold forming.

The same grades of steel are used for hot-rolled sheet and strip for direct use (EN 10 111) and for surface-coated cold-rolled strip (e.g., galvanized steel sheet, EN 10 142) [695]. The microstructure produced by hot strip rolling does not give quite the same cold formability. The properties of coated cold-rolled strip is influ-

enced by various heat treatments (see Chapter 5), but cold formability is practically equivalent to cold-rolled strip. Attention must be paid to the effects of the various coatings on the friction behavior in the drawing gap.

To save weight in vehicle construction and in other areas, e.g., in the building industry, grades of steel have been developed for higher-strength thin flat products which still have good cold forming properties.

Cold-rolled sheet, strip, and thin plate made of general-purpose structural steels with high strength due to the carbon content have poor cold forming properties because of the pearlite in the microstructure. The technique of increasing yield strength by cold rerolling, which increases the dislocation density, impairs the cold forming properties to an unacceptable extent. The introduction of microalloying with Nb, Ti, and V in the early 1960s, giving precipitation-hardened products with greatly reduced carbon content, led to the development of a wide range of high-strength grades of steel with good cold forming properties.

These grades of steel have only small differences in their chemical composition, and are used for cold- and hot-rolled flat products (EN 10 149). The hot-rolled flat products are usually produced by a thermomechanical process, which can be followed by normalizing if required [696]. These steels are now referred to as high-strength low-alloy (HSLA) or low-pearlite steels, and are widely used, especially in the automotive industry [697].

Other methods of improving strength properties without appreciable affecting the cold formability include solid solution hardening, e.g., by increasing the phosphorus content, and the so- called dual-phase steels, in which a pure ferritic matrix structure containing 20 – 30 % dispersed martensite islands is formed [698].

The so- called bake-hardening steels are of particular interest for automotive production [699]. These include cold-rolled uncoated or electrolytically coated sheet, which have low yield strengths and are age-resistant at room temperature as supplied. After press forming, followed by the paint-baking heat treatment (a controlled aging), the yield strength R_e increases from ca. 30 to 50 N/mm^2 (Fig. 322) [700].

Figure 322. Mechanism of the increase in yield strength of a tensile test piece following deformation and heating (bake-hardening)

Figure 323 gives an overview of the various grades of steel for cold-rolled sheet, and includes the properties associated with cold formability and strength [701].

6.2.2.4.2. Steels Suitable for Cold Extrusion and Cold Heading [702]

General. In the cold forming of flat products, the starting material is pressed to form a hollow product or a profile, thereby increasing its surface area. However, in cold extrusion, the starting material, extending into three dimensions, is forced by pressure to yield in all directions (see Section 4.1). The drawing of wire, rod, and tubes also falls under this classification.

Steel can be very suitable for plastic deformation in which the degree of deformation is high, if its microstructure fulfills the necessary requirements. Unalloyed and alloyed grades of steel with up to ca. 1.6 % C are suitable for cold extrusion, as are high-alloy stainless steels.

The many advantages of cold extrusion, e.g., good dimensional control, are described in Section 4.1.3. The process causes work hardening, which is sometimes directly utilized in the finished product. In many applications, a final heat

Figure 323. Mechanical properties of cold-rolled steel sheet grades
Fe P 02 – 05 = deep drawing grades acc. to EN 10 130; Fe P 06 = IF deep drawing grades acc. to EN 10 130; ZstE = HSLA – grades (microalloyed); ZSteP = high strength-grade with increased P content; DP = dual-phase-grades; PM = partially martensitic grade; SSD 220 = high Strength IF-grade (experimental).El_{80} = % elongation at fracture (gage length 80 mm)

treatment is included to give the desired structure and properties.

Properties and Their Measurement. For cold extrusion, the yield stress k_f of a material for a given degree of deformation φ is important. The relationship between these values is represented by the true stress – true strain curve (see Section 6.1.2.1). From the yield stress, the force required for the deformation and the material properties after forming can be estimated. The scatter bands for flow curves of some unalloyed and alloyed steels are shown in Figure 324 [703]. For a given chemical composition, these depend on the microstructure of the material. Understandably, ferrite has the best deformability, influenced by its chemical composition, while the cold deformability of coarsely laminated pearlite is limited. Therefore, steels containing more than ca. 0.15 % C must be heat treated, usually by annealing, to convert the cementite in the pearlite into spheroidal form. The degree of spheroidization and the size of the carbide particles can be used to estimate the formability. Very finely laminated pearlite, e.g., after quenching and tempering or wire patenting, is also very suitable.

Figure 324. Scatter bands of flow curves of unalloyed and low-alloy steels after annealing to form spheroidal cementite [703]

The yield stress is usually determined by a cylindrical compression test. Here, the friction at the surfaces under compression is very important. In practice, the suitability for cold extrusion and the deformability are frequently assessed

simply from the tensile strength, the reduction in area on breaking, and the percentage elongation at fracture. It is essential that the surface of the starting material should be practically defect free for successful cold forming.

Grades of Steel. Cold extrusion and cold heading are used for the manufacture of screws, nuts, and many components used in automobile and machine manufacture, including gear wheels, shafts, piston pins, etc., as well as cold-drawn tubes and wires. The chemical compositions of the grades of steel for these applications must be adapted to cold deformability, i.e., Si and Mn content must be reduced, and undesirable tramp elements such as Cu, Ni, Mo, and P must be excluded by appropriate selection of the raw materials. Small additions of boron improve the hardenability of the steel without increasing the yield stress in the annealed state. A high degree of purity with respect to nonmetallic inclusions is also important, especially long banded inclusions should not be present.

Unalloyed mild steels not intended for heat treatment, and unalloyed and alloyed case hardening and heat-treatable steels with suitable chemical compositions, and after spheroidizing are used in large amounts for cold extrusion and cold heading.

Figure 325. Machinability of free-cutting steels
Machinability index is the machined volume for tool life 8 h, based on a value of 100 % for 9 SMn 28 steel.

6.2.2.4.3. Machining or Free-Cutting Steels [704]

General. The shaping of steel to produce finished products by machining is extremely important. If we exclude sheet stamping, almost all other articles made from steel are formed into their final shape by processes involving the removal of metal, e.g., milling, turning, drilling, screw cutting, sawing, to achieve the required tolerances and surface quality. The costs of these processes are greatly influenced by the machinability of the material (Fig. 325).

Good machining properties are of great importance, especially for the mass production of machinery components, the automotive industry, and also for the operation of computer-controlled automatic lathes or production lines. Good machinability means:

1) Good tool stability at high cutting rates
2) Good breaking properties of the turnings or chippings, so that these can be removed safely
3) Dimensionally accurate and smooth machined surfaces

To meet these requirements, the so-called machining or free-cutting steels were developed some time ago. The formation of short breaking turnings and a very smooth surface was achieved by the addition of sulfur, and, more recently, other elements (Pb, Te, Bi), with a slight increase in phosphorus content. The high levels of these elements can have a harmful effect on technical properties for certain applications, so that the machining steels represent a compromise, and this must be borne in mind when they are used.

Properties and Their Measurement. The use of machining steels is based on their mechanical properties. The distinction is made between low-carbon mild steels which are not intended for heat treatment, and steels which are suitable for case hardening or quenching and tempering (EN 10 087).

Machinability is difficult to quantify, and depends on the interaction of the material of the workpiece with the material of the cutting tool under the actual machining conditions [705]. A large number of test methods have been proposed. These include long-term tests to determine the one-hour cutting speed V_{60}, m/min,

i.e., the cutting speed under prescribed conditions which causes the tool to be worn out after 60 min, and also a quick test to determine the tool failure speed V_E, m/min, with an increased cutting speed. In addition, the shape of the cuttings and the surface finish are assessed.

The distribution and size of the sulfide precipitates (which are of complex composition) in the microstructure is of great importance for the machinability. This distribution is influenced by the metallurgical processes occurring during the production of the steel, and also by the degree of hot rolling. Elements such as tellurium or selenium promote the formation of globular sulfides. Metallographic observations of the microstructure are therefore used in controlling the working method.

Grades of Steel. Low-carbon mild free-cutting steels, not intended for heat treatment, have strength properties like those of Fe 360, and their chemical composition is graded to give varying degrees of machinability. Sulfur content (up to ca. 0.4 %) is approximately ten times that of other steels. The formation of iron sulfide, which leads to "red shortness" on hot forming, is avoided if the Mn content is ca. 1.5 % higher, while the Si content is kept as low as possible (< 0.05 %). Additions of lead (up to 0.1 %) and tellurium improve machinability, but are expensive. Figure 325 shows the effect of various chemical compositions on machinability compared with Fe 360 [704].

With case hardening and heat treatable steels, which are optimized for machinability, the usual principles of alloying apply, but sulfur content is limited to 0.15 – 0.25 %. Machining steels suitable for quenching and tempering are only supplied unalloyed, with carbon content < 0.65 %.

7. Environmental Protection

7.1. Environmental Aspects of Steel Production and Processing

7.1.1. Production of Steel and Steel Products

Large quantities of raw additive and auxiliary materials are used in the production of crude steel and rolled steel products, and large amounts of energy are used in these processes. Substances in the solid, liquid, and gaseous states are potential sources of environmental pollution.

For reasons of economy, the steel industry, especially in Europe, has always attempted to use as little primary energy as possible, to limit the consumption of auxiliary materials, e.g., water, by means of complex recycling systems, and to utilize or recycle byproducts or residues, e.g., slags and mill scale. From the early 1900s, integrated steel plants, in close association with coking plants and rolling mills, have optimized the use of CO-containing blast furnace top gas according to the current state of technology. The use of blast furnace slag for cement and for road construction is very much older than the general interest in environmental pollution. In the last 20 – 30 years, the ever-increasing severity of environmental controls have led to technological developments within the steel industry which have been very successful [706]. However, some of the regulations imposed demand additional capital investment and operating costs whose justification may be dubious, especially when in some countries the regulations imposed are different and, thereby, distort competition. The following discussion is based mainly on available data for the steel industry, and particularly, individual steel plants in the western part of the Federal Republic of Germany.

Figure 326. Carbon consumption in pig iron production

Environmental aspects of the production of pig iron in a blast furnace have already been described (→ Iron, Chap. 4.). Further numerical data on developments during the last 30 years are given here. Figure 326 shows the considerable decrease in the consumption of carbon for reduction purposes in pig iron production [706]; Figure 327 shows the continuous de-

crease in the specific amount of blast furnace slag, and its 100 % use in various applications [707]. The generation of electrical energy from expansion turbines running on blast furnace top gas (Fig. 328) is a further contribution to environmental protection [708].

Figure 327. Development of the specific amount of blast furnace slag and its utilization

Figure 328. Electricity generation by expansion turbines from blast furnace top gas

In a steel melting shop, the amount of dust formed and the possibility of its recovery depend very much on the different steel melting processes, which have undergone many changes (see Section 3.3). The changeover to the oxygen blast process and improvements in dedusting equipment, including secondary dedusting, have led to an emission rate of only 0.7 kg per tonne crude steel in the melting shops of the German steel industry (Fig. 329) [709]. Secondary dedusting, comparable to the "cast house dedusting" at the blast furnace, involves the additional dedusting equipment at different operation points located before and after the converters, e.g., pig iron transfer pit, mixers, deslagging stands; the dedusting equipment consists of stationary or movable hoods and skirts. Figure 330 illustrates the complexity of this additional dust collection in a steel melting shop with three converters [710].

A comprehensive study has shown that the total quantity of dust and sludge collected in the steel plants in North Rhine/Westphalia is 41 kg per tonne crude steel (Fig. 331), of which more than 80 % is reused [708].

The hot waste gas formed in an oxygen converter is used to produce steam in a waste heat boiler in the primary dedusting installation [709], [710]. After further purification and cooling (Fig. 332), it is collected so that its high CO content (68 – 70 %) can be used sometimes after mixing with other gases. Figure 333 shows the significant energy generation which has been achieved in Germany [707].

Slag, an inevitable byproduct in steelworks has been further reduced, reaching 121 kg per tonne crude steel in 1991, of which 87.5 % was utilized [708].

The mill scale occurring in hot rolling mills is a pure iron oxide, and can be reused in sintering plants. However, oil-containing mill scale sludge must be pretreated. Rotary kiln installations to be used for this purpose are in the experimental stage [710].

Control of water consumption in a steel plant is also very important from the environmental point of view. All parts of the production operation involve the consumption of water, sometimes in very large quantities, e.g., for cooling the installations and the products. Attention has always been paid to the development and use of methods for saving water, e.g., the treatment and reuse of water in complex recirculating systems. In 1989, in a steelplant situated near the Rhine, only 3 % of the process water used was fresh water, i.e., 2.5 m^3 fresh water per tonne crude steel (Fig. 334) [706]; the remaining 97 % came

Figure 329. Development of crude steel production and dust emission by the German steel industry

Figure 330. Dust collection in a three- converter steelshop
a) Electrostatic precipitators; b) Converters; c) Mixers

from the recirculation system. Some 83 % of the water used in the steel industry is surface water.

A high proportion of rolled steel production is cold-rolled or coated steel sheet, tinplate, black plate, and cold-rolled electric sheet. The hot-rolled strip for these finished products must be treated in continuous pickling lines to remove the adhering mill scale before the cold-rolling process (see Section 4.3). The used pickling solution is also treated in a recirculating system in which an iron salt, e.g., sulfate, crystallizes, and fresh acid is added, so that only a small fraction of the solution leaves the plant after neutralization. The iron hydroxide sludge, which contains gypsum, cannot be used any further. This also applies to the wash-water in the pickling line, but the amount of wash-water used can be much reduced by appropriate techniques.

7.1.2. Steel Processing and Steel in Use

Steel used in manufacturing as described in earlier chapters, is environmentally a very friendly material.

Figure 331. Origins of dusts and sludges in pig iron and steel production in North Rhine/Westphalia
Amounts in kg per tonne crude steel

Figure 332. Converter gas cleaning and recovery system
a) Converter; b) Skirt; c) Steam boiler; d) Evaporation cooler; e) Dry electrostatic precipitator; f) Fan; g) Reversing valve; h) Flare stack; i) Gas cooler; j) Gasholder; k) Gas mixing station

The processing of steel can certainly involve sound emissions, e.g., during hammering, sheet metal working, and forging. Gases can result when flame cutting and welding steel. However, in both these cases, it is possible to protect personnel at the workplace without great cost and without causing too much inconvenience to the individual. In certain heat treatment processes, e.g., those using molten salt baths, the advice of the manufacturers of the salts or other substances used should be followed, and relevant legal requirements must be observed relating to their handling and disposal.

Environmental problems associated with the use of steel products are practically nonexistent, since steel is a highly recyclable material (see also Section 7.2). Even tinplate is environmentally a friendly packaging material, as it can be separated from waste materials or residues, e.g., from garbage incineration plants, by virtue of the ferromagnetic properties of the steel, and can then be reused.

Figure 335 illustrates the extent to which construction materials are recycled, and in the case of steel this can easily be increased further [711]. The reuse of steel scrap is of great importance for the overall economy. Approximately 60 % less primary energy is required for melting scrap for steel production, than for the smelting of ores [711].

Figure 333. Energy production by the use of converter gas

Figure 334. Internal water circulation

Figure 335. Extent of recycling of various materials

In the last 15 years, the use of sheet with a surface coating, mostly zinc, has increased considerably, both in automotive body manufacture and in other applications. Doubts about the use of zinc-coated steel scrap from these sources are unjustified. Most of the zinc vaporizes during crude steel production, and is recovered in the dust from the filters in the dedusting equipment. If manufacturers dispose of moderately zinc-rich scrap separately, this can be processed and used in suitable electric steel plants, and the zinc can be economically recycled. For this there must be at least 16 % Zn in the filter dust [712].

7.2. Steel Recycling

7.2.1. The Tradition of Steel Recycling

More than 3000 years ago, iron had already been the material foundation for cultural development. It has given its name to an entire epoch. The industrialization is closely linked with the development of the iron and steel industry. Almost all other industries have been directly or indirectly dependent on advances in steel production.

On 28 October 1865, the first iron was smelted by the Siemens – Martin open hearth process using 70 % scrap, so beginning the industrial utilization of scrap [713].

For over a hundred years, a technically and economically viable high-tonnage recycling system has existed for handling production waste and worn-out capital equipment and consumables made of steel and cast iron. For steel scrap, there is a completely closed system for recycling worn-out steel products, any number of times. The recycling process continually yields high quality steel grades without downgrading.

As industrialization progressed and steel production increased toward the 1890s, the demand for raw materials rose. By then, scrap was already an important substitute for the usual raw material in the iron- and steel-producing industry.

7.2.2. Types of Scrap

Listings. In order to provide precise descriptions of the physical and chemical properties required in reusable scrap, an agreed list of scrap grades has been prepared by the steel and steel recycling industry in Europe (Table 28).

Table 28. Extract from the European list of scrap grades (1 July 1995)

Category	Specification	Description	Dimensions	Density, t/m^3	Steriles [a]
Old scrap	E3	Old thick steel scrap, predominantly more than 6 mm thick in size not exceeding 1.5×0.5×0.5 m, prepared in a manner to ensure direct charging. May include tubes and hollow sections. Excludes vehicle body scrap and wheels from light vehicles.Must be free of rebars and merchant bars, free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	Thickness $\geq$ 6 mm$\leq$ 1.5×0.5×0.5 m	$\geq$ 0.6	$\leq$ 1 %
	E1	Old thin steel scrap, predominantly less than 6 mm thick in size not exceeding 1.5×0.5×0.5 m, prepared in a manner to ensure direct charging. If greater density is required it is recommended that maximum 1 m is specified. May include light vehicle wheels, but must exclude vehicle body scrap and domestic appliances.Must be free of rebars and merchant bars, free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	Thickness $<$ 6 mm$\leq$ 1.5×0.5×0.5 m	$\geq$ 0.5	$<$ 1.5 %
New scrap Low residuals, uncoated [b]	E2	Thick new production steel scrap predominantly more than 3 mm thick prepared in a manner to ensure direct charging. The steel scrap must be uncoated unless permitted by joint agreement and be free of rebars and merchant bars even from new production.Must be free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	Thickness $\geq$ 3 mm$\leq$ 1.5×0.5×0.5 m	$\geq$ 0.6	$<$ 0.3 %
	E8	Thin new production steel scrap predominantly less than 3 mm thick prepared in a manner to ensure direct charging. The steel scrap must be uncoated unless permitted by joint agreement and be free of unbound ribbons to avoid trouble when charging.Must be free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	Thickness $<$ 3 mm$\leq$ 1.5×0.5×0.5 m (except bound ribbons)	$\geq$ 0.4	$<$ 0.3 %
	E6	New production thin steel scrap (less than 3 mm thick) compressed or firmly baled in a manner to ensure direct charging. The steel scrap must be uncoated unless permitted by joint agreement.Must be free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.		$\geq$ 1	$<$ 0.3 %
Shredded	E40	Shredded steel scrap. Old steel scrap fragmentized into pieces not exceeding 200 mm in any direction for 95 % of the load. No piece in the remaining 5 % shall exceed 1000 mm. Should be prepared in a manner to ensure direct charging. The scrap shall be free of excessive moisture, loose cast iron and incinerator material (especially tin cans).Must be free of metallic copper, tin, lead (and alloys), and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.		$>$ 0.9	$<$ 0.4 %
Steel turnings [c]	E5H	Homogeneous lots of carbon steel turnings of known origin, free from excessive bushy. Should be prepared in a manner to ensure direct charging. Turnings from Free Turning Steel must be clearly identified. The turnings must be free from all contaminants such as nonferrous metals, scale, grinding dust, and heavily oxidized turnings or other materials from chemical industries. Prior chemical analysis could be required.			[f]

Table 28. (Continued.)

Category	Specification	Description	Dimensions	Density, t/m^3	Steriles [a]
	E5M	Mixed lots of carbon steel turnings, free from excessive bushy and free from turnings Free Cutting Steel. Should be prepared in a manner to ensure direct charging. The turnings must be free from all contaminants such as nonferrous metals, scale, grinding dust and heavily oxidized turnings or other materials form chemical industries.			[f]
High residual scrap	EHRB [d]	Old and new steel scrap consisting mainly of rebars and merchant bars prepared in a manner to ensure direct charging.May be cut, sheared or baled and must be free of excessive concrete or other construction material.Must be free of metallic copper, tin, lead (and alloys), mechanical pieces and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	max. 1.5×0.5×0.5 m	≥ 0.5	< 1.5 %
	EHBM [e]	Old and new mechanical pieces and components not accepted in the other grades prepared in a manner to ensure direct charging.May include cast iron pieces (mainly the housing of mechanical components).Must be free of metallic copper, tin, lead (and alloys) and pieces such as bearing shells, bronze rings and others as well as steriles, to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.	max. 1.5×0.5×0.5 m	≥ 0.6	< 0.7 %
Fragmentized scrap from incineration	E46	Fragmentized incinerator scrap. Loose steel scrap processed through an incinerating plant for household waste followed by magnetic separation, fragmentized into pieces not exceeding 200 mm in any direction and consisting partly of tin coated steel cans. Should be prepared in a manner to ensure direct charging. The scrap shall be free of excessive moisture and rust.Must be free of excessive metallic copper, tin, lead (and alloys) and steriles to meet the aimed analytical contents.Refer to points B) and C) of the general conditions.		≥ 0.8	Fe content ≥ 92 %

[a] Weight percentage of steriles not adhering to the scrap that are left in the vehicle after unloading by means of magnetic separation.[b] Coated material must be declared.[c] Free from contaminants (nonferrous metals, scale, grinding dust, chemicals, excess oil).[d] Rebar and merchant bar must be calssified separately due essentially to the copper content which could place them in a category with old scrap and new scrap of low residual grades.[e] Mechanical and engine components must be classified separately principally due to their Ni, Cr, and Mo content which could place them in a category with thick old scrap and heavy new scrap of low residual grades.[f] To date, there is no clear method to determine these values.

These defined grades apply only to carbon steel scrap. The following general requirements are included in the European list of scrap grades of 1st July, 1995. The scrap must be:

1) Prepared in a manner to ensure direct charging
2) Handleable magnetically
3) Free from elements harmful to the smelting process

Plant Scrap. Plant scrap is produced in the manufacture of steel and of rolled finished products. It is directly reused in the steelworks.

New Scrap. New scrap arises in steel processing industries as production waste. It is usually returned to steelworks and foundries by the recycling industry.

Capital Scrap. Capital scrap is composed of steel, cast steel, and cast iron originating from used commodity and industrial goods. There are three types, classified according to origin:

1) Demolition scrap
2) Automobile scrap
3) Collected scrap

The development of the amounts of plant scrap, new scrap, and capital scrap is illustrated in Figure 336, with estimated future figures, assuming that 70 % of steel consumption is returned to the material cycle after a period of 20 years.

7.2.3. Scrap Processing

7.2.3.1. Separation

Steel is used in engineering, plant construction, vehicles, building industry, shipbuilding, household appliances, packaging, etc. When products that consist mainly of steel are no longer usable, they are usually processed by the steel recycling industry. The composition and dimensions of scrap are usually such that it cannot be used in steelworks and foundries in its original state. Appropriate processes must therefore be used for:

1) Size reduction
2) Separation from other materials
3) Classification into grades

A unique characteristic of steel and iron scrap is that it can easily be recovered from accompanying materials by its magnetic properties, enabling the iron- containing constituents to be returned to steelworks and foundries in a high state of purity.

7.2.3.2. Shearing Machines

Large pieces of scrap can be size-reduced by shearing machines. Even before the World War I guillotine shears were used for this purpose.

Further developments led to the larger and faster alligator shears, and then to the hydraulic machines used today, where the scrap is charged by a crane into a feeding bed. The feeding bed is usually provided with a prepress which compresses the scrap so that even bulky material can be pushed under the blades of the shears. Size reduction of, e.g., freight cars industrial equipment, and large components, including material from shipbreaking and other heavy demolition work, is carried out with shears with a compression force of up to 2000 t and blades up to 2.50 m wide [714].

7.2.3.3. Presses

Scrap presses are used to densify clean steel scrap, e.g., production waste from rolling mills and steel processing industries, to facilitate transportation and charging, and to reduce it to the specified dimensions.

In the early 1920s, slow mechanical screw presses with large vertical boxes and small charging holes were developed. These were able to bale light collected scrap and new sheet scrap.

Mechanical baling presses were followed by high-pressure hydraulic presses with large charging boxes. This hydraulic equipment produces high-density bales of the size needed for steel production plants, e.g., converters and electric furnaces, and for the melting facilities of the foundry industry. The usual bale sizes are: $30 \times 30 \times 30$ cm and $40 \times 40 \times 60$ cm for the foundry industry, and $60 \times 60 \times 150$ cm for the steel industry [715].

Figure 336. Development of arisings of plant scrap, new, and capital scrap, with estimated future figures

7.2.3.4. Shredders

Increasingly, scrap is no longer in pure form, but combined with other materials. Examples include old vehicles and household appliances, which contain considerable amounts of plastics, glass, rubber, nonferrous metals, and other materials. Shredders (Fig. 337) have been used by the steel recycling industry since the mid 1960s to produce automobile and collected scrap that meets the requirements of the steelworks.

A shredder functions on the principle of the swing-hammer mill. The products fed to the shredder are broken down to pieces not larger than fist-sized, and are then fed to an air separator to remove the light waste fraction, which includes plastics, textiles, and cardboard. An electromagnetic drum or band separator separates the steel scrap from the nonferrous metals and coarse impurities (heavy waste fraction). The materials removed by the air separator, which cannot, at present, be recycled (shredder residues) must be disposed of. This is expensive, and is likely to become more so. Shredding provides a means of recovering the iron and steel from used products with purity ca. 98 %, so that they can be returned to the raw material cycle.

7.2.4. Factors Influencing Recycling

7.2.4.1. Alloy Steels

In steel production, the properties of various grades of steel are achieved by adding alloying elements. Alloy steel can also be returned to the material cycle, if it is sorted according to chemical composition. The alloying elements are retained when the scrap is melted, and new alloy steels can be produced from this metal.

7.2.4.2. Surface Coatings

Steel is surface coated to give the properties required, i.e., surface quality, stress condition, and corrosion protection. Surface coatings can be either metallic (e.g., zinc) or nonmetallic. The latter include organic coatings (plastic or paints) and inorganic coatings (cement mortar or enamel) [716].

Smelting of zinc-coated steel scrap during steel production is the present state of the art. As zinc boils at 907 °C and steel melts at 1400 – 1500 °C, the zinc vaporizes from the melt and is collected as zinc oxide in dedusting plants. If the zinc content of the steelworks dust is ca. 16 %, it is profitable to recover the zinc [717], [718].

Figure 337. Operating principle of a shredder

Before scrap recovered from steel with a nonmetallic coating can be returned to steel production, it is usually processed by shredding, or cold shock treatment to remove adhering materials from the scrap, as these are harmful to the smelting process, or can lead to inadmissible emissions.

7.2.4.3. Pretreatment of Used Steel Products

Steel products and components at the end of their lives are often associated with impurities, or are attached to other materials. To prevent the unwanted materials from being returned to steel production along with the scrap, pretreatment and purification are necessary, e.g., removal of oil from chips arising from the processing of steel, which are classified as new scrap.

Pretreatment of used products that consist mainly of steel is often also necessary for disposing of or recycling the other materials in the products, e.g., the disposal of old cars. In the initial dismantling, the batteries of the old vehicles are removed to return the lead to a separate material cycle. This also prevents the lead from contaminating waste tips when the shredder residues are dumped. For the same reason, fuel, oil, gear, differential, and shock absorbers, and brake fluid and coolant are recovered before the old cars are shredded. In refrigerators, freezers, and air conditioning equipment, the cooling liquids are recovered to prevent their escape into the atmosphere.

Tinplate packaging, e.g., for foodstuffs, consists of very thin tinned steel sheet. The scrap from tinplate cans is processed by the steel recycling industry, and returned to steel production where it is used without problems. The consumption of tinplate packaging and the extent of its recovery for recycling in Germany is shown in Figure 338.

Figure 338. Consumption and partial recycling of tinplate packaging in Germany

Steel sheet packaging for commercial use, e.g., barrels or canisters, can be contaminated with organic or inorganic residues from the filling (paints, varnishes, oils, or adhesives). They must be emptied as far as possible and then pro-

Figure 339. World trade in scrap 1990

cessed by, e.g., shredding, cold shock treatment, or centrifuging, enabling the scrap to remain in the material cycle, provided that the chemical and physical quality requirements of the steel industry are met.

7.2.5. Economic and Logistic Aspects

7.2.5.1. Scrap Consumption

According to the International Iron and Steel Institute (IISI), total world consumption of scrap, including scrap used in foundries, was 369×10^6 t in 1996. Most of this (335×10^6 t) was used in steel production. In 1996, total world crude steel production was 753×10^6 t [719]. Hence, the average consumption of scrap per tonne crude steel produced was ca. 450 kg. Electric steel plants accounted for 226×10^6 t scrap. Thus, ca. 60 % of scrap was consumed by electric steel plants.

7.2.5.2. World Market for Scrap

Scrap is an international commodity with a free price structure. Scrap arisings and consumption vary greatly from one country to another. The proportions of the various steel production processes in different countries have a considerable influence on scrap consumption, and hence on the flow of imports and exports. In electric steelworks, 100 % scrap can be used for steel production. In 1996, the average usage of scrap in German electric steelworks was 1031 kg per tonne crude steel.

In oxygen steel production, pig iron produced in the blast furnace is oxidized together with scrap in a converter. The average usage of scrap in 1996 in the Federal Republic of Germany was 181 kg per tonne crude steel for this process [720]. In the production of high quality steel grades shredded scrap for cooling is preferred because of its high purity and the small lump size.

The most important flows of scrap in world trade in 1990 are illustrated in Figure 339.

Figure 340. World steel production from 1950 (selected regions)
Smooth curve is 5-year average
Data Supplied by the Statistisches Bundesamt (German Federal Bureau of Statistics) and the International Iron and Steel Institute (IISI)

7.2.5.3. Infrastructure and Logistics

The task of the steel recycling industry is to take responsibility for iron and steel scrap, i.e., to transport, store, process, and deliver to steelworks and foundries a high-quality raw material.

The recycling system offers one particular advantage: The collecting points are installed in all countries. They collect scrap according to its origin, lump size, and impurity levels. The structure of these organizations varies:

1) Small-scale and collection service
2) Medium-sized scrap wholesale traders
3) Organizations supplying scrap to steelworks

Scrap is transported by rail, water, and road. To enable prompt delivery, the steel recycling industry has made considerable investments in handling and transportation facilities.

The demand for scrap is not constant, so the scrap recycling industry maintains stocks containing the equivalent of the purchasing requirements of steelworks for ca. 2 months. Thus, the industry has taken over an important function in balancing scrap arisings with consumption [721].

8. Economic Aspects

8.1. World Steel Production, Consumption, and Trade

From the World War II to the early 1970s, world crude steel production grew at an average annual rate of ca. 5.5 %. Since then, the rate has been only 1 % (Fig. 340). The number of steel-producing countries increased from ca. 30 to ca. 90.

The largest steel-producing companies, with their 1992 production, are shown in Table 29.

Table 29. Leading steel producers 1992

Company	Country	Production, 10^6 t
Nippon Steel	Japan	25.10
Usinor Sacilor	France	21.10
Posco	Korea	20.01
British Steel	United Kingdom	12.39
NKK	Japan	10.89
Ilva	Italy	10.60
Thyssen	Germany	10.13
Kawasaki	Japan	10.00
Sumitomo Metals	Japan	9.97
Sail	India	9.70
Bethlehem	United States	9.60
US Steel	United States	9.50

Of the total world crude steel production, 721×10^6 t in 1992, 345×10^6 t (48 %) was produced by 50 companies in the western world. There are also large steelworks in the countries of the former Soviet Union. Some of these are listed in Table 30.

Table 30. Steel production in the former Soviet Union

Steelworks	Country	Capacity, 10^6 t/a
Magnitogorsk	Russia	16.2
Chereporets	Russia	14.0
Krivoy Rog	Ukraine	13.9
Lipetsk	Russia	9.9
Nizhiny Tagil	Russia	8.3

Figure 341. Steel consumption
A) 1974; B) 1992Source: IISI, Brussels

After the political changes of the early 1990s, steel production in these countries decreased considerably, i.e., from 216×10^6 t in 1987 to 124×10^6 t in 1993.

The strong growth of the world steel industry starting in the 1970s was due to the high demand for steel in western Europe, Japan, and eastern Europe. In these regions, steel consumption expanded by almost 7 % per annum. In the United States, the rate was only 2 %. Consumption by the developing countries grew rapidly from small beginnings, at > 8.5 % per annum.

In the last 30 years, considerable regional changes in steel consumption and production have occurred. Approximately one-fifth of steel consumption and 15 % of steel production is associated with the developing regions (Fig. 341). China has also moved ahead. Japan improved its position until the early 1970s, but its share of the world volume has stagnated since then. Europe and the United States are producing a considerably lower proportion than 20 years ago.

Regional shifts have increased the extent to which the developing countries have become self-sufficient, but since then, demand has grown more rapidly than supply. The traditional exporters, e.g., Japan and the European Community, have relied more strongly on their domestic markets. The United States has been a net importer since 1959. The relationship between production and market supply has developed as shown in Table 31.

Brazil has become one of the largest net exporters. Meanwhile, the contribution by eastern Europe and the former Soviet Union to the world total has decreased since the end of the communist planned economy (Fig. 342).

Figure 342. Crude steel production by region 1950 – 1992

World steel exports have grown more rapidly than world production (Fig. 343) because of variations in the regional distribution of demand and production. In the 1970s and early 1980s,

Table 31. Steel production and consumption 1970 – 1992

Region	Production Consumption Balance 10^6 t			Production Consumption Balance 10^6 t			Production Consumption Balance 10^6 t		
	1970			1980			1992		
European Community	146.2	132.9	13.3	141.9	119.9	22.0	129.1	115.2	13.9
Western Europe	161.9	153.9	8.0	161.2	142.1	19.1	153.8	135.3	18.5
United States	119.3	127.3	−8.0	101.5	118.6	−17.1	84.3	100.3	−16.0
Japan	93.3	69.9	23.4	111.4	79.0	32.4	98.1	84.0	14.1
Industrialized countries	397.4	374.0	23.4	406.9	366.2	40.7	366.9	340.4	26.5
Developing countries	22.1	42.2	−20.1	56.7	94.4	−37.7	117.2	147.7	−30.5
Brazil	5.4	6.0	−0.6	15.3	14.3	1.0	23.9	9.1	14.8
Eastern Europe	40.1	41.5	−1.4	61.2	59.6	1.6	32.4	21.1	11.3
Former Soviet Union	115.9	110.2	5.7	147.9	150.4	−2.5	117.0	115.0	2.0
China	18.0	22.5	−4.5	37.1	43.2	−6.1	80.0	83.1	−3.1
World	595.7	592.8	2.9	715.9	718.8	−2.9	720.5	714.8	5.7

the volume of international trade in steel tended to grow at the same rate as general world trade, but in recent years, the volume of steel trade has not increased. The increasing self-sufficiency of new producing countries tends to have a braking effect, but in the area of products and grades, and as a result of competition for customers by the manufacturing companies, active interchange across national boundaries is likely in future.

Figure 343. World steel exports, production, and trade from 1970 to 1995
1970 figures = 100 %
a) World trade (all products); b) Steel exports; c) Crude steel production
Source: IISI; Dresdner Bank

Steel exports from Japan have decreased from $> 30 \times 10^6$ t in the mid-1980s to 18×10^6 t in 1991. Most significant is the collapse of trade among the former COMECON countries – ca. 15×10^6 t reduction in the exchange volume. As shown by the high uptake by China from the international market in late 1992/early 1993, relatively large fluctuations in world steel exports are likely.

A summary of the largest exporting and importing countries in 1991 is given in Table 32.

Table 32. World trade in steel 1991

Country	Exports, 10^6 t	Country	Imports, 10^6 t
Germany	19.6	Germany	16.8
Japan	17.9	United States	14.3
Belgium/Luxembourg	14.3	France	10.3
France	12.0	Italy	10.3
Brazil	10.9	Japan	9.0
Italy	9.0	Taiwan	8.7
United Kingdom	8.0	South Korea	8.5
Korea	7.7	United Kingdom	5.6
United States	5.8	Iran	5.5
Netherlands	5.7	Netherlands	5.2
Former Soviet Union	5.4	Belgium/Luxembourg	4.7
Spain	4.8	Former Soviet Union	4.6

An important feature of the steel industry that affects investment decisions is the extent of export orientation of steel manufacturers. In the industrialized countries, the important steel consumers, e.g., engineering and motor vehicle manufacturers, export a high proportion of their steel- containing products (Table 33).

In countries with very high steel exports, e.g., Germany and Japan, the so- called indirect for-

Table 33. Direct and indirect steel exports of selected regions

	Direct export, 10^6 t rolled steel	Indirect export, 10^6 t rolled steel	Direct production, %	Indirect consumption, %
European Community				
1979	65.7	32.0	53.4	32.4
1990	70.2	37.7	58.9	35.8
Japan				
1979	30.7	12.0	30.8	17.1
1990	16.6	20.4	16.9	23.0

eign steel trade affects the trend of development of steel consumption and per capita steel consumption considerably (Table 34). For these two countries in 1990, indirect exports and imports of rolled steel resulted in a net balance, estimated at 9.3 and 19.4×10^6 t. These examples show the importance of the basic conditions for fair international trade.

Table 34. Steel consumption in selected countries 1990

Country	Consumption, kg rolled steel per capita
West Germany	482
France	285
United Kingdom	244
Sweden	336
Japan	751
Brazil	60

The demand for steel, the most important construction material for industry (including the construction industry) and handicrafts, is mainly determined by overall economic development, and hence by capital investment and external trade in steel-containing goods. The optimism which, in the early 1970s, led to investment in steel capacity was considerably dampened after the first oil crisis of 1974–75. The second large increase in the price of oil in 1979, and the increased attention to environmental problems slowed down the economic growth of the western industrialized countries, where the standard of living had reached a remarkably high level. Future growth is likely to be essentially calmer.

8.2. Steel Intensity and Weight Saving in Steel

Steel consumption depends on the state of the overall national economy, especially on investments and foreign trade. In the early stages of industrialization, steel consumption grows at a rate out of proportion to that of the national product. Later, the so-called steel intensity decreases, and steel consumption grows more slowly than the national product (Fig. 344). The most important reasons include:

1) Weight savings in steel manufacture by design optimization, making use of lighter and qualitatively superior steels. The 320 m Eiffel Tower was built of 7000 t steel in 1889, but today would require only 2000 t. A 165 m mast for a radio link station can be built today with only 210 t steel.
2) The use of different materials within the broad area of rolled steel products, e.g., greater use of flat products in place of long products, and the use of increasingly thin sheet for flat products (Fig. 345).
3) Replacement of steel by other materials, e.g., light metals or plastics, e.g., in automobiles. The proportion of steel and iron has decreased from 75 % in the 1970s to 65 % in the early 1990s. The aluminum content has grown from 3 % to 5 %, and plastics from 6 % to 10 %. It is likely that steel will continue to be the most important constituent of automobiles, remaining at ca. 60 %
4) A combination of steel with other materials is often the best solution (e.g., sandwich construction).
5) The reason for most of the reduction in specific steel consumption is the improved productivity of the steel industry itself, and not the replacement of materials.
6) With increasing maturity of a national economy, the fraction of the total national product accounted for by commercial services increases, and the fraction accounted for by manufacturing and heavy basic materials decreases. In 1960, the proportion of the West German national product accounted for by

manufacturing was 53 %, in 1980 it was 43 %, and in 1992, 37 %. Mining, basic materials, and manufactured goods contributed 32 %, 30 %, and 23 % to the turnover of manufacturing business in these years.

8.3. Capital Investment and Subsidies

The steel industry, a capital-, energy-, and raw-material-intensive industry, has always striven to improve productivity and cost effectiveness. Improvements in industrial plant design production methods, and installations for recovering or recycling waste heat, waste gases, electricity, and water have been of central importance. The high intensity of capital investment brought steep cost reductions whenever it was possible to fully utilize the capacities of very large installations. Consequently, from the 1950s to the 1970s, large integrated steelworks were central to strategic planning. Optimization of locations with respect to raw material supplies (coastal steelworks) or large marketing regions (Rhine, Ruhr) was emphasized. Technical development at that time mainly provided the measurement and control techniques essential for large blast furnaces, large converters, strand casting plants, and large rolling mills, and the electronic support for the organization of production. Innovations and improvements have contributed to reductions in the capital cost per tonne steel produced, in specific energy consumption, in raw and auxiliary materials costs, and in general running costs.

In modern steelworks, the production of 1 tonne rolled steel requires 1.1 t crude steel, whereas 20 years ago it required 1.3 t. Consequent savings of raw steel are ca. 80×10^6 t/a worldwide. There is a further possible saving of 40×10^6 t by further modernization, assuming the same volume of rolled steel.

However, intensity of capital investment compared with other branches of industry is still relatively high. In 1990, it was 170 000 € per installation, which compares with only 60 000 € in engineering (Fig. 346). Capital investment constitutes just 20 % of the cost of steel produced in West Germany. Personnel costs account for ca. 25 %. The sum of these costs is only slightly influenced by short-term market fluctuations.

Figure 344. Steel consumption from 1980
A) Developing countries (a); Industrialized countries (b);B) Korea (a); Turkey (b); Japan (c)From calculations supplied by IISI

Large production units cannot be throttled back at will. However, as the steel market reacts extremely strongly to economic change (rising demand in boom periods, falling demand during recessions), suppliers have problems in matching supply to demand, especially in times of weak markets. The result is intense competition between suppliers for small market volumes at falling prices. As long as businesses can build up a financial reserve in good economic times, short-term falls in demand can be coped with. However, this becomes much more difficult if medium-term demand forecasts are over-optimistic.

For a long time, so-called mini-steelworks have become the cost and price leaders among producers of light-section steel products (e.g., rod and wire rod). For this product area, the favored production scheme is electrosteel processing of scrap and small rolling mills. This reduces capital costs, and gives flexibility in matching market fluctuations.

New technology, organization systems, and the resulting increase in productivity and economic efficiency have also influenced price. Steel prices have risen considerably more slowly than those of the average industrial product, or have even fallen, and the severe fluctuations in international quotations during economic cycles have at least been no worse than those the 1970s (Fig. 347).

Figures for Spain from 1984Source: Wirtschaftsvereinigung Stahl (Industrial Association for Steel)

There are very high barriers preventing steel-making installations with overcapacity from getting out of the market. In western Europe since the mid 1970s these have become even higher, as state intervention distorts competition, making reduction in capacity very difficult. Large subsidies have ensured survival, especially of nationalized undertakings (Fig. 348). Reduction in capacity is lagging behind the true need, and finance for capital investment in modernization has continued to be available (Table 35).

Private undertakings can only combat such subsidized competition for a limited period, if there is no countervailing policy to avoid subsidized companies increasing their market share.

The steel politics of the European Community since the middle 1970s exemplify the disastrous effects of state intervention in a market economy. The decisions of the European Commission and the Council of Ministers during the steel crisis of 1991 – 1993 show that there is a gulf between the broad political aims of a European Union and the real economic, financial, and structural politics of the member countries.

In some steel-producing countries (e.g., the United Kingdom and Brazil) governments have become unwilling to pay high subsidies, on the grounds that they block the possibilities for investment in alternative projects. Privatization of nationalized steel undertakings has gone ahead.

8.4. Future Prospects

New perspectives are opening up in the steel industry through further technical developments in casting and rolling technology. A new generation of continuous production lines, from crude steel to products close to final dimensions, may considerably reduce the specific capital costs both of flat steel products and of heavy profiles, increasing the flexibility of undertakings to match economic fluctuations. At the same time, productivity can be significantly improved. Different configurations of the supply structure are likely to become available to the large suppliers of flat steel products, who are themselves advancing these technical developments, i.e., independent small and medium manufacturing units, or a combination of several plants with an efficient source of crude iron and steel from large units.

In recent years, small and medium-sized steelworks, mainly based on scrap, have been in favor, but there are limits to this development. Increasing amounts of scrap are available for steel production, but growing world steel demand is likely to require the smelting of iron ore.

Thus, from the economic point of view, many opportunities present themselves for steel as a competitive material for the future.

1. Nomenclature

Steroids are compounds that contain a cyclopenta[α]-phenanthrene ring skeleton which, when fully hydrogenated, is called gonan or steran.

5α-Gonan or 5α-Steran

This parent structure can be modified by opening one or more bonds, by ring enlargement, or by ring contraction. The carbon atoms are numbered and the rings are indicated by letters (Fig. 1). There are angular methyl groups on C-10 and C-13. If, for instance, C-10 does not bear a methyl group, the resulting compounds are called 19-norsteroids.

Figure 1. Steroid numbering

For chiral centers at carbon atoms 8, 9, 10, 13, and 14, the absolute stereochemistry (Fig. 2) is specified in the parent names. Rings B, C, and D are predominantly *trans* linked. All atoms or groups below the plane of the ring are represented by a dashed line and the letter α, and those above the plane are indicated by a solid line and the letter β. If the configuration is unknown, a wavy line and the letter ξ is used.

Figure 2. Steroid stereochemistry
R = Oxygen functional group or alkyl group, which may be substituted

Hydrogen atoms at 8, 9, and 14 are not shown in the structural formula as long as there is *trans* linkage. The position of the hydrogen at C-5 should always be indicated. The parent compounds are shown in Figures 3 and 4.

5α-Estrane or 19-Nor-5α-androstane

5β-Androstane

Figure 3. Parent compounds with no side- chain at C-17

The great variety of natural and synthetic steroid compounds results from the presence of double bonds and various substituents on the ring skeleton and the side- chain. The systematic names are formed according to IUPAC rules [1]. Trivial names are permitted for some steroids, mostly natural steroids with high biological activity.

Owing to the chair conformation of the cyclohexane ring (Fig. 5), substituents on the steroid skeleton are either approximately in the plane of the ring, equatorial (e), or vertical, axial (a). The chemical reactivity depends on this conformation [2].

2. Sterols

The first compounds of this class to be studied in detail were isolated from the unsaponifiable parts of animal and plant oils and fats. They are solid crystalline secondary alcohols with 26–30 carbon atoms, and can occur as such or as fatty acid esters and glycolipids. They were given the group name sterols (Greek, *stereos*, solid).

Figure 7. 5α-Sterols

Cholesterol (**1**) is the most widely distributed sterol. Its name indicates that it is the main constituent of human gallstones. It is found in many animal tissues, in wool fat, and in plants. A survey of the literature on the occurrence, isolation, determination, metabolism, etc., is presented by Cook [3]. In humans and other mammals, cholesterol is a metabolic precursor of gallstones [4] and steroid hormones (→ Hormones, Chap. 3.1.). At a low developmental level, diverse, poorly separable sterol mixtures occur, but in the course of evolution, cholesterol becomes increasingly important until, in vertebrates, it is practically the only sterol [5]. In the 1930s, cholesterol served as the starting compound for androgen synthesis [2]. Although it was for some time replaced by sapogenins, it has become important again, owing to progress in microbiological fermentation [6]. Other important starting sterols for the partial chemical synthesis of compounds of the androstane and estrane series are stigmasterol (**2**) and β-sitosterol (**3**) (→ Hormones, Chap. 3.2.1.). Both sterols are contained, e.g., in soybean oil. Further phytosterols include brassicasterol (**4**) (→ Fats and Fatty Oils, Chap. 2.5.) and campesterol (**5**) [7], spinasterol (**6**) from spinach [8] or alfalfa [9], and the yeast sterols zymosterol (**7**) [10] and faecosterol (**8**) [7]. The sterols isolated from invertebrate sea animals exhibit structural changes, especially in the side chain. 24-Methylenecholesterol (**9**), spongesterol (**10**), poriferasterol (**11**), clionasterol (**12**), and chondrillasterol (**13**) occur in various fungi, and 24-dehydrocholesterol (**14**) occurs in the goose barnacle [2]. A cyclopropane ring in the side-chain, as in gorgosterol (22*S*,22*R*,23*R*,24*R*) [*29782-65-8*] (**15**), appears to be characteristic of a whole class of marine steroids [11].

15

Calysterol [*57331-04-1*] (**16**) contains a cyclopropene ring [12].

16

A list of natural steroids is given in [7, Table 19]. Some cholesterol derivatives, e.g., cholesteryl benzoate, form liquid crystals (→ Liquid Crystals, Chap. 3. → Liquid Crystals, Chap. 3.6. → Liquid Crystals, Chap. 3.7.).

2.2. Vitamin D

It was recognized around 1920 that rickets could be cured by cod-liver oil or solar irradiation. The antirachitic constituent of cod-liver oil was found to be a fat-soluble compound which was called vitamin D. It was also discovered that plant oils became antirachitic on irradiation [13], and that the potentially active compounds were in the unsaponifiable part [14], which consisted of a mixture of sterols. Whereas cod-liver oil apparently contained preformed vitamin D, the phytosterol mixture contained a provitamin. It was found [2] that ergosterol is the percursor of vitamin D_2 (ergocalciferol) (→ Hormones, Chap. 5.1.) and 7-dehydrocholesterol yields vitamin D_3 (cholecalciferol). Vitamin D_3 is metabolized to 1α,25-dihydroxyvitamin D_3 (calcitriol) in the liver and kidney. Calcitriol is the agent responsible for calcium and phosphate transport in the body. Thus, cholecalciferol and its biologically active metabolites must be regarded as vitamins as well as hormones (→ Hormones, Chap. 5.2. → Hormones, Chap. 5.3.). Since the only abundant source of vitamin D is fish-liver oil, syntheses are of great importance [2]. Attempts were made to find other antirachitic substances by irradiating sterols that differed from ergosterol only in the side-chain [15]. Methods for the synthesis of calcitriol have been developed more recently, and attempts are being made to find derivatives which are more efficient in separating the systemic effect on calcium metabolism from the antiproliferative activity (→ Hormones, Chap. 5.4.). In the last few years, side-chain analogs have been tested for possi-

ble use in some forms of cancer and in psoriasis [16–19].

2.3. Methyl Sterols

"Sterols" with additional methyl groups on the ring skeleton are found together with cholesterol in many plants and fungi, and, abundantly, in the wool fat of sheep. The best known are lanosterol [*79-63-0*] (**17**) and agnosterol [*472-29-7*] (**18**) from wool fat [20], and kryptosterol from yeast [21].

17

18

The identity of kryptosterol and lanosterol was established later [22]. Although it is analytically difficult to distinguish these compounds from the real sterols, they are regarded as triterpenes, which are mainly pentacyclic isoprenoid compounds with 30 carbon atoms. Lanosterol plays a key role in the biosynthesis of cholesterol. Acetate is converted to squalene in ten steps with the help of enzymes, and the transformation of squalene to cholesterol involves another 19 enzymatic steps [23, 24]. Squalene gives rise to lanosterol, which is then converted to ergosterol, an important sterol in many fungi. Substances which interfere with steroid biosynthesis are used in plant protection to control pathogenic fungi (→ Fungicides, Agricultural, Chap. 8.6.). Other compounds of the lanostane type are mainly 4,4,14α-trimethyl derivatives of cholestane or ergostane; some are acids (Fig. 8), e.g., eburicoic acid (**19**), polyporenic acid C (**20**), tumulosic acid (**21**), and pinicolic acid (**22**). They all occur in parasitic fungi that live on wood [2]. Others have a cyclopropane ring at position 9, 10 (Fig. 9), e.g., cycloartenol (**23**) from the latex of the fruit of *Artocorpus integrifolia,* cyclolaudenol (**24**) from opium, and cycloeucalenol (**25**), with only one methyl group at C-4, from eucalyptus. The significance of cycloartenol in the biosynthesis of steroids in higher plants is comparable to that of lanosterol [25].

	Δ	3	16	24	CAS No.
Eburicoic acid (**19**)	8	β-OH		$=CH_2$	[*560-66-7*]

Cycloeucalenol (**25**)	24-methylene	[*469-39-6*]

Figure 9. 9,19-Cyclo lanostane compounds

Compounds of the euphane and lanostane types are epimers with respect to carbon atoms 13, 14, and 17. Thus, euphol, obtained from the resin of a species of *Euphorbia*, corresponds to 13α, 14β, 17α-lanosterol. The 20-epimer is tirucallol [26].

The cucurbitacins exhibit natural bactericidal activity, and have been tested for cytotoxic and antitumor activity [27], and are regarded as kairomones (→ Biological Control). The fusidane series should also be mentioned here, fungal metabolites which have antibiotic properties and are especially active in staphylococcal infections. These compounds include fu-

sidic acid [*6990-06-3*] (**26**) (→ Antibiotics) and helvolic acid [*29400-42-8*] (**27**).

26

27

The stereochemical linkage, *trans-syn-trans-anti-trans*, which forces ring B into the boat form, is unusual [28].

3. Bile Acids

The bile acids are among the oldest known steroid compounds. In 1828, cholic acid was isolated in the impure state by the saponification of ox bile. The first careful studies were carried out by STRECKER in 1848 [29]. Later, it was primarily WIELAND and coworkers who studied the constitution and configuration of the bile acids. They are mostly mono-, di-, or trihydroxy derivatives of cholanic acid [2,4]. Choleinic acid, the second bile acid to be discovered, is a molecular compound consisting of 1 mol fatty acid and 8 mol deoxycholic acid [30]. Deoxycholic acid reacts with many acids, esters, alcohols, ethers, phenols, and hydrocarbons to form molecular compounds, now collectively known as cholenic acids. They are very stable, and X-ray analysis showed that they are inclusion compounds [31]. Apocholic acid (8, 14-dehydrodeoxycholic acid) behaves in the same way [32]. Only cholic acid and deoxycholic acid (from ox bile) and hyodeoxycholic acid (from pig bile) can be used as starting compounds for syntheses, because they are available in large quantities from natural sources. Even microbiological methods of cortisone production, starting with plant steroid sapogenins, have not been able to completely replace cholic acid and deoxycholic acid as base materials (→ Hormones). Whereas mammalian bile acids are derived from 5β-cholanic acid, bile acids with side- chains extended by 3 – 4 carbon atoms have been found in the bile of phylogenetically old species of toads and crocodiles, e.g., 3α-7α-dihydroxy-5β- cholestanic acid in the bile of *Alligator mississipiensis.* The bile alcohol scymnol [*6785-34-8*] (**28**) was isolated from shark bile, and has also been found in other species of fish and frogs [33].

28

A survey of the bile acids found in fish, amphibia, reptiles, birds, and mammals is presented by HASLEWOOD [34–36]. Bile acids with extended side- chains are regarded as the phylogenetic precursors of mammalian bile acids [37].

The bile acids are the end-products of cholesterol metabolism in the liver [38]. First, changes occur at the ring skeleton. The side- chain is then subjected to oxidative degradation [39]. The bile acids possess a hydrophobic and a hydrophilic part. They form water-soluble micelles with lecithins and water-insoluble lipophilic food components; thus, fatty acids, monoglycerides, steroids, fat-soluble vitamins, and cholesterol are kept in solution in the bile [40]. However, if the concentration of bile acids falls below a certain value, gallstones can form. Gallstones differ in chemical composition; ca. 10 – 20 % are pure cholesterol stones [41], which can be dissolved by oral administration of chenodeoxycholic acid [*474-25-9*] (**29**) or ursodeoxycholic acid [*128-13-2*] (→ Gallbladder and Liver Therapy, Chap. 2.). Ursodeoxycholic acid can also be used in the treatment of liver cirrhosis [42] and to ameliorate the symptoms of biliary reflux disease [43]. Cholic

acid [*81-25-4*], deoxycholic acid [*83-44-3*], and dehydrocholic acid [*81-23-2*] are used as choleretics (→ Gallbladder and Liver Therapy, Chap. 1.). The sodium salt of deoxycholic acid is used on a small scale to improve the resorption of drugs, e.g., absorption of insulin through the nasal mucous membrane [40].

Chenodeoxycholic acid (Fig. 10) is produced on an industrial scale from cholic acid according to the method of FIESER [44]. Ursodeoxycholic acid can be obtained from chenodeoxycholic acid (**29**) by oxidation of the 7α-OH group to the 7-ketone, followed by reduction with alkali metal in amyl alcohol or liquid ammonia [45], by the selective microbiological hydroxylation of lithocholic acid [46], or from cholic acid [47].

4. Steroid Hormones

Estrone [*53-16-7*] was the first sex hormone to be obtained in the pure state [48]. A short time later, estriol [*50-27-1*] was isolated from the urine of pregnant women [49]. In 1934, four different teams succeeded almost simultaneously in preparing pure progesterone [50–53]. The preparation of testosterone [*58-22-0*] was achieved in 1935 [54]. At the same time, investigation of extracts of the adrenal cortex intensified. The research groups of REICHSTEIN and KENDALL introduced the practice of naming their isolated substances by letters. By 1943, as many as 28 steroids had been identified, including cortisone, cortisol, cortexolone (Reichstein S), 11-dehydrocorticosterone, corticosterone, and deoxycorticosterone [55]. Aldosterone was isolated in 1953 [56]. Industrial production of pregnenolone from diosgenin, which occurs in the root of the Mexican plant *Dioscorea*, began in 1940 [57]. The discovery in 1948 that cortisone had a strong effect on the symptoms of arthritis, initiated an intensive search for further anti-inflammatory steroids and the development of new methods for the commercial production of cortisone. The discovery of the reduction of phenol ethers to dihydro compounds (1950) made possible the production of 19-norsteroids from estrone methylether [58]. Many steroid reactions had been described by 1950, but little was known about the reaction mechanisms. BARTON showed that many rules that had been established empirically could be rationalized by the concept of axial and equatorial bonds [59]; conformation analysis gave steroid research a strong impetus. It was also recognized that UV [60] and IR spectra [61] are valuable in structural elucidation.

Another important physical quantity for the characterization of steroid compounds is optical rotation. Steroids exhibit several asymmetric centers; all naturally occurring steroids are optically active (→ Hormones, Chap. 3.1.).

Nuclear magnetic resonance sprectra, mass spectrometry, and X-ray analysis are also used for structure determination [62].

Steroid hormones are divided into three main physiological groups:

1) Sex hormones
   Estrogens (→ Hormones, Chap. 3.5.)
   Gestagens (→ Hormones, Chap. 3.7.)
   Androgens (→ Hormones, Chap. 3.6.)
2) Adrenal steroids
   Glucocorticoids
   (→ Hormones, Chap. 4.4.)
   Mineralocorticoids
   (→ Hormones, Chap. 4.9.)
3) Calcium-regulating sterols
   (→ Hormones, Chap. 5.1.)
   Vitamin D
4) Insect skin-shedding hormones

Cholesterol is the common precursor in the biosynthesis of the first three groups (→ Hormones, Chap. 3.1.). Apart from steroid compounds with hormonal activity, some compounds act as hormone antagonists. Depending on the mode of action, distinction is made between substances that occupy specific receptors and those that block hormone production. Thus, not only are antiestrogens known (→ Hormones, Chap. 3.5.4.), but also antiandrogens (→ Hormones, Chap. 3.6.3.), antigestagens (→ Hormones, Chap. 3.7.5.), and antagonists of mineralocorticoids (→ Hormones, Chap. 4.9.).

In the synthesis of steroid hormones, four processing modes are distinguished:

1) Partial chemical synthesis from natural products (→ Hormones, Chap. 3.2.)
2) Microbiological degradation of sterols (→ Hormones)
3) Total synthesis (→ Hormones, Chap. 3.4.)
4) Isolation from natural sources

Figure 10. Production of chenodeoxycholic acid

The starting materials for partial chemical synthesis must contain the steroid nucleus, they must be convertible to steroid hormones via intermediates by simple chemical reactions, and they must be available in sufficient quantities. The most important starting substances are cholesterol, stigmasterol, β-sitosterol, and diosgenin (→ Hormones, Chap. 3.2.1.) as well as bile acids, ergosterol, and hecogenin (→ Hormones, Chap. 4.8.2.). The most important compounds obtained are dehydropregnenolone, progesterone, androstenolone, and estrone (→ Hormones, Chap. 3.2.1.). The androgenic steroids also have a more-or-less strong anabolic activity which can be intensified by chemical modification of the steroid nucleus. However, some androgenic activity always remains (→ Hormones, Chap. 3.6.4.). The glucocorticoids, another group of steroid hormones, have also been subjected to various chemical modifications. Attempts have been made to reduce the mineralocorticoid side effects. The introduction of a double bond at position 1,2 gave compounds with glucocorticoid, anti-inflammatory, and antiallergenic activity 4 – 5 times that of cortisone (→ Hormones, Chap. 4.10.). The introduction of 9α-halogen (→ Hormones, Chap. 4.10.2.), 16α-hydroxyl (→ Hormones, Chap. 4.10.3.), 6α-methyl (→ Hormones, Chap. 4.10.4.), 16α-methyl (→ Hormones, Chap. 4.10.5.), 16-methylene (→ Hormones, Chap. 4.10.6.), 6α-fluoro, 6α- chloro, and 6α, 9α-difluoro substituents (→ Hormones, Chap. 4.10.7.) produced further improvements. In 1964, Raspé and coworkers found that 16α-methylcorticoids lacking the 17-hydroxyl group are still relatively strong anti-inflammatory substances, with very low mineralocorticoid activity (→ Hormones, Chap. 4.10.8.). The 11β-hydroxyl group has been replaced by a halogen (→ Hormones, Chap. 4.10.9.). Other derivatives of well-known, active corticoids gave a series of compounds with little or no systemic activity, so these compounds can be very successful in treating dermatosis in children (→ Hormones, Chap. 4.11.). It has not been possible to find either the exact mechanism of the anti-inflammatory and immunosuppressive activity of the glucocorticoids (→ Dermatotherapeutic Agents), or a new class of compounds to replace the glucocorticoids.

The insect skin-shedding hormones are completely different. Each stage of skin shedding from larva to pupa to adult insect is subject to hormonal control. Whereas growth is controlled by the juvenile hormones (→ Biological Control, Chap. 5.1.1.), the skin-shedding hormones are steroids. In 1954, the first 25 mg of a crystalline skin-shedding hormone was isolated from the silkworm *Bombyx mori* [63]. This substance, α-ecdysone (**30**), was found to be a steroid by chemical and X-ray studies [64]. A very similar compound, β-ecdysone (**31**), also occurs in the silkworm. Other skin-shedding hormones, or zooecdysones (Fig. 11) have been isolated from insects or crustaceans,

e.g., inokosterone (**32**) and makisterone A (**33**) from crabs [65] and 26-hydroxy-β-ecdysone (**34**) from the tobacco hornworm *Manduca sereta (L)* [66]. Shortly after the elucidation of the structure of α-ecdysone (**30**), a number of steroids with skin-shedding activity, the phytoecdysones, were also found in plants [67]. They are widely distributed, and occur in relatively large quantities [68]. By 1979, a total of 47 different phytoecdysones were known, and most of the zooecdysones had been found in plants as well [69]. The first synthesis was published by Schering AG – Hoffmann LaRoche [70]. This was followed by several improvements and other starting materials were used [71–73]. The direct introduction of a 2,7-diene-6-one group from 3β-tosylate-5-ene resulted in a considerable shortening of the synthetic pathway [74].

Name	20	24	25	26	CAS No.
α-Ecdysone (**30**)			OH		[*3604-87-3*]
β-Ecdysone (**31**)	OH		OH		[*5289-7-7*]
Inokosterone (**32**)	OH			OH	[*15130-85-5*]
Makisterone A (**33**)	OH	CH_3	OH		[*20137-14-8*]
26-Hydroxy-β-Ecdysone (**34**)	OH		OH	OH	[*52717-49-4*]

Figure 11. Zooecdysones

5. Sapogenins

Plant glycosides that form a soapy foam in water are called sapogenins. They are composed of an aglycon, sapogenin, and one or more sugars (→ Saponins, Chap. 3.1.). Apart from a few exceptions, the sugar moiety is bound to the steroid through a 3β-OH group. The first saponins were derived from digitalis preparations and were called digitonin and gitonin, and the corresponding aglycons, digitogenin and gitogenin. Even later, the names were often derived from the plants from which the sapogenins were isolated. Raw plant extracts were used as detergents because they are neither alkaline nor precipitable by hard water. Saponin preparations without cardiac effects have been used in fire extinguishers, and as fish poisons. Although fish are numbed or killed by saponins, they are still edible because the oral consumption of saponins is not harmful to humans. The structures of the aglycons are not as varied as those of the cardiac glycosides. These steroids belong predominantly to the spirostanes (→ Saponins). The most important is diosgenin, the starting compound for the partial synthesis of steroid hormones (→ Hormones, Chap. 3.2.1.). Hecogenin was also of importance for a time (→ Hormones).

6. Steroid Alkaloids

Steroid alkaloids occur in both plants and animals. Plant steroid alkaloids are widely distributed, and have various structures, depending on the plant species. Funtumine [*474-45-3*] (**35**), conessine, holarrhimine Δ^5[*468-31-5*] (**36**), and holarrhidine 5α-H [*82182-51-2*] (**37**) have been isolated from certain species of *Holarrhena*.

The first three compounds were considered as starting substances for the commercial synthesis of steroids [75], but without success.

35

36, 37

Irehdiamine A is found in *Funtumia elastica*, and cyclobuxine D and buxocine C [76–78] in certain species of *Buxus*. The solanum alkaloids solasodine (→ Alkaloids, Chap. 14.), solanidine

[*80-78-4*] (**38**), and tomatidine [*77-59-8*] (**39**) should also be mentioned [79].

38

39

Solasodine and tomatidine have been converted to 16-dehydropregnenolone by the Marker process [80]. The solanum alkaloids occur in plants in the form of glycosides (→ Saponins, Chap. 3.2.).

All the alkaloids mentioned above have an essentially unchanged steroid skeleton. Attempts have been made to prepare solanum alkaloids with the help of biotechnology, but without commercial success [81].

In the veratrum and fritillaria alkaloids, ring *C* is contracted to a five-membered ring and ring D is enlarged to a six-membered ring. Hence, they are *C*-nor-*D*-homosteroids [82, 83]. Jervine and verticine (→ Alkaloids, Chap. 14.5.), as well as the ester alkaloid protoverine [*76-45-9*] (**40**) belong to this group.

40

The ester alkaloids contain 7 – 9 oxygen atoms, esterified with organic acids, such as acetic, angelic, veratric, vanillic, or tiglic acid. Protoverine possesses vasodilative properties.

The animal steroidal alkaloids are poisonous, and are excreted though the skin. The main poisons of the salamander are samandarin [*467-51-69*] (**41**) and cycloneosamandione [*631-72-1*] (**42**).

41

42

Samandarin poisoning leads to cramps and respiratory paralysis. In fact, salamanders can die from their own poison if it enters the circulatory system. The poison of a small, brightly colored frog, *Phyllobates amotaenia*, is used as an arrow poison in Colombia. The active substances are 20-esters of batrachotoxins with various pyrrole carboxylic acids [84]. One of the most poisonous substances known is 2,4-dimethylpyrrole-3- carboxylic acid ester. Its subcutaneous LD_{50} is 2 µg/kg in the mouse, compared to 500 µg/kg for strychnine.

7. Steroid Lactones

The steroid lactones include the cardenolides and bufadienolides, aglycons of the cardiac glycosides (→ Cardiac Glycosides and Synthetic Cardiotonic Drugs, Chap. 1., → Cardiac Glycosides and Synthetic Cardiotonic Drugs, Chap. 2.) as well as the holothurigenins, withanolides, and antheridiols. The sea cucumber excretes saponins that are toxic to fish, and exhibit hemolytic and oncolytic properties [85]. Acid hydrolysis gives the holothurigenins, e.g., seychellogenin [*24041-68-7*] (**43**).

43

The withanolides are found in the Solanacae plant family [86]. The best-known representative is withaferin A [*5119-48-2*] (**44**).

44

Antheridiol [*22263-79-2*] (**45**) is the first specifically acting steroid sex hormone to be discovered in plants [87].

45

Antheridiol is secreted by the female plant and brings about formation of antheridial hyphae on the male plant of *Achyla bisexualis* [88], which lives in water.

1. Introduction

Strontium belongs to group 2 of the periodic table and is one of the alkaline earth metals. Strontium [*7440-24-6*], with atomic number 38, lies between calcium and barium in this group. Strontium was first discovered by A. Crawford in 1790. The discovery of strontium carbonate, which was originally thought to be barium carbonate, is associated with a lead mine located in Strontian, Scotland, hence the name strontium. In 1791 T. C. Hope confirmed Crawford's discovery, distinguishing strontium carbonate from calcium and barium carbonates.

In 1808 H. Davy [8] produced strontium metal from strontium carbonate originating from the Strontian deposit. Davy produced an oxide from the carbonate, and electrolyzed a mixture thereof with mercuric oxide to produce a strontium amalgam.

2. Properties

Strontium metal is silvery white and lustrous, but it readily forms a white surface coating when exposed to air and water. Strontium is allotropic and displays three crystal structures; at temperatures below 215 °C it is face-centered cubic. The crystal system properties are summarized in Table 1 . Some other properties are listed below:

Atomic number	38
Atomic mass	87.62
Stable isotopes, % abundance	
^{84}Sr [*15758-49-3*]	0.56
^{86}Sr [*13982-14-4*]	9.86
^{87}Sr [*13982-64-4*]	7.02
^{88}Sr [*14119-10-9*]	82.56
Density, g/cm^3	2.63
Melting point, °C	768
Boiling point, °C	1381
Heat of fusion, kJ/kg	104.7
Electrical resistivity, μΩ/cm	22.76

Table 1. Strontium crystal structures

Temperature, °C	Structure	Atomic radius, pm	Lattice constants, pm	
			a	*c*
< 215	fcc	213	607	
215 – 605	hcp	202	431	705
> 605	bcc	195	484	

Strontium is generally more reactive than magnesium and calcium and less reactive than barium. Strontium reacts with H_2O, O_2, N_2, F_2, and S producing compounds which correspond to its valence of two.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a25_321

Common practice for the analysis of strontium is based on the use of spectral emissions. Strontium and strontium compounds impart a bright crimson color to a flame. Some of the lines useful in the quantitative analysis of strontium are listed below (wavelength in nm):

Arc spectra	460.7, 421.6
Spark spectra	407.8, 421.6
Flame photometry	460.7, 407.8
Atomic absorption	460.7, 407.8

Strontium, while less reactive than the alkali metals, is a strong reducing agent and requires appropriate handling. Strontium reacts vigorously with water to form SrOH, liberating H_2 in the process.

3. Occurrence

Strontium is present in the earth's crust at an average concentration of 0.04 %, and is therefore 15th in abundance. In seawater it is the 10th most abundant element, having a concentration of 0.0008 % [9].

Of the naturally occurring strontium compounds, only the minerals strontianite (strontium carbonate, $SrCO_3$) and celestite (strontium sulfate, $SrSO_4$) are of economic importance.

Celestite can be formed as a direct precipitate in a series of marine salt deposits. Hydrothermal formation is also possible [10]. In addition, it seems possible that strontium sulfate could be formed by modification of primary strontium-bearing minerals (aragonite, calcite, anhydrite), whereby part of the strontium included in the crystal lattice is liberated and then precipitated as celestite by sulfate-containing solutions [11]. Strontianite can be formed both as a primary mineral from the hydrothermal phase and as a secondary mineral from, e.g., celestite [12].

Celestite occurs principally as nodules, lenses, beds and materials filling crevices in sedimentary rocks such as carbonates, gypsums, clays, and evaporites. The economic importance of celestite is considerably greater than that of strontianite.

Very large, exploited deposits occur in Spain, Mexico, Turkey, China, and Iran. There are much less important deposits in Algeria, Cyprus, Argentina, and Morocco. Mining in the United Kingdom, the traditional producer, ended in 1992. Little is yet known of the deposits and their extraction in the former eastern bloc [13], [14].

4. Mining and Processing

Celestite ores are obtained by both open-cast and underground mining. In most cases, only coarsely intergrown rich ores are worked, which can be further enriched by hand picking to give a material containing >90 % $SrSO_4$. Demands for increasing purity in chemically produced strontium salts together with the growth of mechanized mining techniques necessitate a continually increasing amount of processing.

Finely divided impurities are removed by desliming. By means of density separation, celestite ($\varrho = 3.8 - 3.9$ g/cm^3) is separated from limestone, quartz, gypsum, and dolomite, which have densities of <3 g/cm^3, giving end products containing >95 % $SrSO_4$. In Spain, a flotation plant for separating finely intergrown celestite ores has been in operation since 1990. The introduction of this technology has markedly increased the number of deposits worldwide that can be profitably worked.

Many important deposits cannot be mined because of unacceptably high levels of barium and deposit-specific trace elements that cannot be removed by available processing technologies.

Economic Aspects. Whereas strontianite was the principal starting material used in the production of strontium compounds between 1870 and 1920, it has now been almost completely replaced by celestite for this purpose.

Practically the only use for celestite is the production of other strontium compounds. It is used only to a small extent as a white filler in competition with ground barite (barium sulfate).

Table 2. Estimated production of celestite (10^3 t)

Country	1988	1991
Spain	45	70
Turkey	55	65
United Kingdom	20	2
China	20	25
Mexico	40	90
Iran	10	20
Morocco	2	4

World production of celestite in the early 1990s was estimated at ca. 250 000 – 300 000 t/a. The most important producing countries, with their production figures, are listed in Table 2.

5. Chemical Digestion of Ores

Reduction with Carbon. Celestite, flotated or ground to 0.1 – 1 mm, is chemically reduced according to the equation

$$SrSO_4 + 2\,C \longrightarrow SrS + 2\,CO_2$$

The reduction is carried out at 1100 – 1200 °C with coal in a rotary kiln, heated by fuel oil, natural gas, or coal dust in countercurrent flow. The conditions used depend in particular on the type of celestite and its impurities.

The light gray to grayish-black crude strontium sulfide (75 – 80 % SrS) produced is extracted with hot water. The insoluble solids are removed in a series of thickeners. The solution obtained is generally used to produce strontium carbonate.

Reaction with Sodium Carbonate. Ground celestite ($SrSO_4$) is converted to strontium carbonate by adding it to hot sodium carbonate solution. Numerous variations of this process have been proposed. Typically, an excess of Na_2CO_3 solution is used. The crude product so obtained is not usually acceptable without further treatment. A product sufficiently pure for most applications is obtained by dissolving the crude material in hydrochloric acid, neutralizing with sodium carbonate solution to precipitate iron and aluminum, filtering, and reprecipitating with caustic soda. This process also produces impure sodium sulfate solution as a byproduct which must be further treated or disposed of. The high consumption of sodium carbonate is a further drawback.

Other Processes. Celestite can be reacted with ammonium carbonate in a continuous countercurrent reactor to form strontium carbonate and ammonium sulfate [15]. The ammonium sulfate is treated with calcium oxide or calcium carbonate to form calcium sulfate, ammonia, and carbon dioxide, which are reused for producing ammonium carbonate.

In the Odda process for producing orthophosphoric acid, phosphate rock is reacted with nitric acid. The strontium present in many types of phosphate rock is converted to strontium nitrate, which remains in the insoluble residues if the concentrations of HNO_3 and $Ca(NO_3)_2$ are kept within certain limits. It can then be recovered by extraction with water.

6. Strontium Compounds

Like the compounds of the other alkaline earth metals, those of strontium are white or colorless. The sulfate and the carbonate are of low solubility, being intermediate between the corresponding compounds of calcium and barium in this respect.

Strontium compounds give a striking carmine red color to a flame. This property is used both for the rapid detection of strontium compounds and in pyrotechnics. Quantitative analysis of the industrial strontium compounds is usually carried out by means of titrimetry, X-ray fluorescence spectroscopy, and atomic absorption spectroscopy.

6.1. Strontium Carbonate

Strontium carbonate [*1633-05-2*], $SrCO_3$, M_r 147.63, ϱ 3.70 g/cm^3, *mp* 1497 °C (6.99 MPa), forms rhombic crystals (aragonite type) below 924 °C, and hexagonal crystals (calcite type) above this temperature. Its solubility at 25 °C is 10^{-3} g/100 mL.

Strontium carbonate is produced from strontium sulfide [*1314-96-1*], SrS.

Precipitation by Carbon Dioxide. Strontium carbonate is precipitated from the clarified solution of strontium sulfide (see Chap. 3) with carbon dioxide. Strontium carbonate and hydrogen sulfide are formed.

$$SrS + CO_2 + H_2O \longrightarrow SrCO_3 + H_2S$$

The carbon dioxide is obtained from natural wells or from industrial processes.

The reaction is carried out in gas-tight reactors, and is so controlled that the hydrogen sulfide produced has a low CO_2 content. The hydrogen sulfide is converted to sulfur in a Claus plant (→ Sulfur, Chap. 6.).

Precipitation with Sodium Carbonate. Sodium carbonate can be used instead of carbon dioxide in the above reaction.

$$SrS + Na_2CO_3 \longrightarrow SrCO_3 + Na_2S$$

In addition to strontium carbonate, a dilute solution of sodium sulfide is formed, which is concentrated to give a 60 % solution; the solidified product is marketable.

The choice of production method depends on the comparative availabilities of carbon dioxide and sodium carbonate, and the opportunities for exploiting the byproducts sulfur and sodium sulfide.

The two processes lead to products with different properties. The impurities in the strontium carbonate depend partly on the raw materials used. Also, the concentrations, temperatures, and reaction times lead to different values of bulk density, particle size distribution, and concentrations of sulfur and heavy metals.

The strontium carbonate powder is often converted into granules in a further process.

Quality Specifications. Typical specifications for strontium carbonate from the two precipitation processes are as follows:

$SrCO_3$	98.0 – 98.5 %
$BaCO_3$	1.0 – 2.5 %
Sulfur (as SO_3)	0.3 – 0.5 %
HCl insolubles	0.1 – 0.6 %
Fe_2O_3	0.005 – 0.01 %
For powder:	
Bulk density	0.4 – 1.2 g/cm^3
Fraction of particles <3 µm	95 – 100 %
For granules:	
Bulk density	1.2 – 1.8 g/cm^3
Grain size	
>850 µm	0 – 5 %
<150 µm	5 – 15 %

Transport. Strontium carbonate is stored in silos, and transported in 25 or 50 kg multi-ply paper sacks, 1 t big bags, or silo wagons. Strontium carbonate is not listed as a dangerous material in current regulations.

Uses. Strontium carbonate is by far the most important industrial compound of strontium. Its main use is in the manufacture of X-ray-absorbing glass for cathode ray tubes. Strontium carbonate is also used in the manufacture of ceramic permanent magnets (strontium ferrite), for removing lead from solutions of zinc sulfate in the electrolytic zinc process, and for the production of strontium metal, electroceramics, and oxide superconductors [14], [16]. Strontium carbonate is also the starting material for the production of other strontium compounds. For example, heating strontium carbonate with carbon in an electric furnace gives strontium oxide, which is used for production of strontium metal.

Between 1980 and 1990, world consumption of strontium carbonate increased from ca. 80 000 t/a to >150 000 t/a. Percentage consumption of strontium carbonate in 1990 was [14]:

Glass for cathode ray tubes	74
Electroceramics	12
Pyrotechnics	5
Electrolytic zinc extraction	2
Other uses	7

6.2. Strontium Nitrate

Strontium nitrate [*10042-76-9*], $Sr(NO_3)_2$, M_r 211.63, ϱ 2.986 g/cm^3, *mp* 570 °C, forms face-centered cubic crystals.

Below 29.3 °C, the solid phase in equilibrium with an aqueous solution on strontium nitrate is strontium nitrate tetrahydrate, $Sr(NO_3)_2 \cdot 4\,H_2O$. The solubility of strontium nitrate (in grams per 100 g solution) at various temperatures is as follows:

Temperature, °C	20	29.3	60	105
Solubility	40.7	47.0	48.3	51.2

Production. Strontium nitrate is obtained by dissolving strontium carbonate in 60 % nitric acid.

If the solution is maintained above ca. 30 °C during the evaporation, colorless crystals of the anhydrous compound are formed. After the carbonate, the nitrate is the strontium compound produced commercially in the largest quantities.

Uses. Strontium nitrate has long been used in pyrotechnics and as a component of signalling devices. Related devices are used in the United States and Japan as alternatives to portable electric lamps in motor trucks [14].

Packaging and Storage. Strontium nitrate is packed in 50 kg polyethylene bags. The following transport regulations apply:

RID/ADR:	Class 5.1, 22 C
IMDG Code:	Class 5.1, UN no. 1507

6.3. Strontium Chloride

Strontium chloride [*10476-85-4*], $SrCl_2$, M_r 158.53, ϱ 3.052 g/cm^3, *mp* 875 °C, forms cubic crystals. Its solubility at 20 °C is 34.5 wt %.

Production. Strontium chloride is obtained by dissolving strontium carbonate in concentrated hydrochloric acid. The hexahydrate, $SrCl_2 \cdot 6\,H_2O$ [*10025-70-4*], is formed on crystallizing below 61 °C. On dehydration, the hexahydrate dissolves in its water of crystallization at 61 °C. After passing through the di- and monohydrate stages, strontium chloride becomes fully dehydrated at 320 °C.

Uses. Strontium chloride is mainly used as an intermediate in the production of other strontium compounds. Compared with the sulfide, it has the advantage of not reacting with oxygen and carbon dioxide, which facilitates industrial handling.

Strontium chloride hexahydrate is used in toothpastes for sensitive teeth [17].

Strontium chloride is not classified as a dangerous material in transport regulations.

6.4. Strontium Chromate

Strontium chromate [*7789-06-2*], $SrCrO_4$, M_r 203.61, ϱ 3.895 g/cm^3, forms monoclinic crystals.

Strontium chromate is included in dangerous materials regulations [18] (symbol: T).

Production. Strontium chromate is produced by precipitating a solution of chromate ions with a strontium salt, or by reacting strontium hydroxide solution with chromic acid.

Uses. Strontium chromate (strontium yellow) is used as an anti-corrosion primer for aluminum and its alloys in aircraft and ship construction [19].

7. Strontium Metal

Production. Commercial strontium production relies on a variant of the Pidgeon process, exploiting the reaction proposed by GUNTZ [20]:

$$4\,SrO + 2\,Al \longrightarrow 3\,Sr + SrO \cdot Al_2O_3$$

Produced under vacuum, the strontium evolves as a gas and is transported through the production retort to a cooler end where precipitation occurs. The strontium precipitates as a solid and when the production cycle is complete the vacuum is broken and the product removed. Strontium is produced by Timminco Limited in Canada, Pechiney Electrometallurgie in France, and Cal-Stron Corporation in the United States. In addition, production may well occur in the CIS and China but the extent of production, if any, is unknown.

Strontium metal is commercially available as pure metal, and as an alloy with aluminum or aluminum and magnesium.

A typical percentage chemical analysis of commercial strontium is as follows:

Sr	99.0 min.
Mg	0.20
Ca	0.10
Ba	0.50
Na	0.07
N	0.03
Al	0.01
Fe	0.015

Transportation, Storage, and Safety. Due to its reactive nature strontium must be handled with care. The pure metal and the commercial eutectic alloy, 90 % Sr – 10 % Al, are classified as alkaline earth metals n.o.s. (not otherwise specified), UN no. 1393, for the purposes of transportation [21]. This classification is indicative of materials requiring special approved packaging for transport. These two forms of commercial strontium are packed under an inert atmosphere to prevent formation of an oxide coating. Strontium is a strong reducing agent and forms explosive hydrogen gas when in contact with water. Strontium is therefore classified as a flammable solid. Hence strontium is a Class 4.3 material, i.e., one that emits a flammable gas on contact with water. Strontium should therefore be stored in a well ventilated

dry place, avoiding all contact with water. It is recommended that protective gloves and glasses should be worn when handling pure strontium. However, commercial alloys of strontium, such as the Sr – Mg – Al master alloy or the family of aluminum – strontium master alloys which contain up to 10 percent strontium do not require these special precautions.

Uses. Metallic strontium and master alloys containing strontium have experienced significant expansion in application in modern foundry practice. In aluminum foundries strontium is used as an additive to Al – Si alloys to enhance their mechanical properties and improve the machining performance. Strontium improves the mechanical properties of Al – Si castings by changing the morphology of the eutectic silicon phase. In an unmodified Al – Si alloy this eutectic silicon phase precipitates as coarse acicular plates, which causes the casting to exhibit poor mechanical properties. Modification causes the silicon to assume a fine, interconnected fibrous morphology, resulting in higher tensile strength and greatly improved ductility. Impact resistance and machining characteristics are also enhanced through modification.

The optimum strontium level to achieve the best possible mechanical properties in hypoeutectic Al – Si alloys is 0.005 – 0.015 percent strontium [22]. The impact of strontium is also influenced by the solidification rate, with faster rates producing better properties.

Early foundry practice utilized sodium as a modification agent. In 1920, Pacz outlined a process by which the solidification structure of Al – Si alloys was modified by the addition of sodium to the melt. The sodium addition produced a fibrous eutectic structure which showed improved mechanical properties, especially elongation.

The principal drawback with sodium is that the effect of the sodium rapidly dissipates as sodium is lost by evaporation and/or oxidation during the holding of the molten alloy.

Strontium has the advantage of imparting a semi-permanent modifying effect, as it is less prone to the fading observed with sodium. This allows the production of so called pre-modified aluminum ingots which can be sold to end users. Nevertheless, many foundries for economic and logistical reasons chose to modify in house.

Strontium also improves the properties and processing of wrought aluminum alloys.

Strontium appears to act on both the mechanical and forming properties of 6xxx series wrought alloys. These improvements are reported to occur when, in the presence of strontium, the complex intermetallic compounds found in these alloys are precipitated in more favorable crystal structures [23]. Under normal or non-strontium treated conditions the formation of β-AlFeSi intermetallic is favored. The presence of this compound can contribute to surface defects upon extrusion of 6xxx series alloys. The controlled addition of strontium promotes the less detrimental α-AlFeSi leading to better surface quality in the extrusion and faster extrusion speeds.

In the 7xxx series of wrought alloys it has been reported that strontium, at levels of at least 0.005 percent, refines the intermetallic phases, including Mg_2Si, Al – Cu – Mg, and Al – Cu – Fe. When these phases are refined the alloy has enhanced toughness, finer grain size, and can be processed more quickly due to shortened homogenizing times compared to strontium-free alloys [24].

In an aluminum alloy sheet which requires high formability the presence of strontium is reported to reduce the number of intermetallic precipitates. This improves the alloy's formability and reduces the incidence of edge cracking [25].

In ferrous metallurgy strontium finds application as a component in certain foundry grades of ferrosilicon, used as inoculants in gray iron casting. The addition of 0.65 – 1.05 % strontium controls the carbon structure in an iron casting and inhibits the chill. The chill, which is in some cases a desired phenomena, is a rapidly solidified zone in a casting where the formation of mottled iron (cementite and graphite) is favored over a pearlite structure with graphite. By controlling the chill the foundry may be able to decrease the minimum section size in a casting keeping it free from the brittle carbides which would most likely form without inoculation. In addition strontium-bearing inoculants are particularly effective in helping to control internal shrinkage in these castings and thereby enhancing the pressure tightness of the casting [26].

8. Toxicology

Strontium carbonate is not considered to have any dangerous properties. There are no known occupational diseases associated with handling strontium carbonate, the most important industrial strontium compound.

The strontium ion is slightly toxic. The toxic action of strontium compounds is thus closely associated with the anion of the compound concerned. Strontium behaves similarly to calcium both chemically and biologically. The biological effects of strontium and its compounds have been described in detail [27].

Strontium is deposited preferentially in the bones and teeth of the human body. Strontium salts are not readily absorbed via the intestinal tract.

Symptoms of acute toxicity are excessive salivation, vomiting, colic and diarrhea, and possibly respiratory failure.

The LD_{50} values (oral) of various strontium salts (nitrate, hydroxide, chloride, fluoride) are >2000 mg/kg body weight [28].

Strontium nitrate was administered orally in the food of rats at a concentration of 50 mg/kg (1030 ppm daily for 8 weeks) without harmful effects. Strontium lactate at a level of 16 000 ppm, after more than one year, caused temporary cessation of growth and reduction of bone mineralization [14].

The inhalation of ca. 50 mg/m^3 strontium nitrate (4 h daily for one month, particle size mainly $< 5\,\mu$m) was less well tolerated by male rats. As well as local effects on the respiratory tract, functional and histological systemic changes took place, especially in the liver and kidneys [29].

Strontium oxide and strontium hydroxide have a strongly irritant effect on the skin and mucous membranes, especially the eyes.

No special hygienic measures are taken in the industrialized countries, except in the case of strontium chromate. The TLV/MAK value for strontium nitrate is 1 mg/m^3, and for strontium sulfate and strontium carbonate, 6 mg/m^3 [30]. However, these values are still the subject of debate.

Strontium chromate is included in the list of MAK values for carcinogenic industrial materials in Group III, A 2 [31]. The TRK of strontium chromate ($SrCrO_4$) is 0.1 mg/m^2, calculated as CrO_3.

1. Introduction

Styrene [*100-42-5*], also known as phenylethylene, vinylbenzene, styrol, or cinnamene, $C_6H_5{-}CH{=}CH_2$, is an important industrial unsaturated aromatic monomer. It occurs naturally in small quantities in some plants and foods. In the nineteenth century, styrene was isolated by distillation of the natural balsam storax [1]. It has been identified in cinnamon, coffee beans, and peanuts [2], and it is also found in coal tar.

The development of commercial processes for the manufacture of styrene based on the dehydrogenation of ethylbenzene [*100-41-4*] (→ Ethylbenzene) was achieved in the 1930s. The need for synthetic styrene – butadiene rubber (→ Rubber, 3. Synthetic, Chap. 2.1.) during World War II provided the impetus for large-scale production. After 1946, this capacity became available for the manufacture of a high-purity monomer that could be polymerized to a stable, clear, colorless, and cheap plastic (→ Polystyrene and Styrene Copolymers). Peacetime uses of styrene-based plastics expanded rapidly, and polystyrene is now one of the least expensive thermoplastics on a cost-per-volume basis.

Styrene itself is a liquid that can be handled easily and safely. The activity of the vinyl group makes styrene easy to polymerize and copolymerize. When the appropriate technology became available through licensors styrene was quickly transformed into a bulk-commodity chemical, growing to a world-wide capacity estimated at 17×10^6 t/a in 1993 and $18\text{x}10^6$ t/a in 1995 [54]. For reviews of this important industrial history see [3], [4].

2. Physical Properties

Styrene is a colorless liquid with a distinctive, sweetish odor. The most important physical properties of styrene are summarized below. Data appearing in the literature are not always consistent, varying as a consequence both of the method of measurement and the purity of the monomer. Most manufacturers make available the physical properties they regard as valid [5]. Important general physical properties of styrene monomer are as follows:

M_r	104.153
bp	145.15 °C
fp	−30.6 °C

Vapor pressure is a key property in the design of styrene distillation equipment. It is essential that the same data set be used for both column design and column assessment. Vapor-pressure data we believe to be accurate are as follows:

Temperature, °C	Vapor pressure, kPa
20	0.6
50	3.2
80	12.2
100	25.7
145.2	101.3

Antoine equation:

$$\log_{10} P = [6.08201 - 1445.58/(209.43 + T)]$$

Styrene is miscible with most organic solvents in any ratio. It is a good solvent for synthetic rubber, polystyrene, and other non- cross-linked high polymers. Styrene is sparingly soluble in polyvalent hydroxy compounds such as glycol and diglycol monoethers. Styrene and water are sparingly soluble in each other (Table 1).

The composition of the azeotropic mixture at standard pressure is ca. 66 wt % styrene and 34 wt % water, and the minimum boiling point is 94.8 °C.

Important parameters for monitoring the production and use of styrene are the refractive index and the density (Table 2). Table 3 lists supplementary physical properties of styrene.

Table 1. Mutual solubilities, styrene/water, wt %

3. Chemical Properties

The most important reaction of styrene is its polymerization to polystyrene, but it also copolymerizes with other monomers. The copolymerization with butadiene to give Buna S synthetic rubber (emulsion styrene – butadiene rubber, E-SBR) was the reaction that led initially to the development of the styrene industry. Other characteristic reactions are described below. The literature has been well summarized [3], [6], [7].

Oxidation of styrene in air is of special importance. The reaction leads to high molecular mass peroxides by way of free radicals. Styrene is also

oxidized to various other compounds, including benzaldehyde, formaldehyde, and formic acid. Other typical alkene reactions are observed with stronger oxidizing agents:

Styrene can undergo addition to the double bond of the side chain as well as substitution in the ring. Treatment with bromine in the cold gives addition, leading to styrene dibromide. This crystallizes well, and has been used both to characterize styrene and to determine it quantitatively in solution [8]. Splitting off hydrogen bromide from styrene dibromide gives α-bromostyrene, while phenylacetylene can be formed by heating with calcium oxide. Addition of chlorine forms styrene dichloride, which can be converted to α-chlorostyrene and β-chlorostyrene by elimination of hydrogen chloride.

The halohydrins are important intermediates in preparative chemistry. They react with alkali to form styrene oxide, while further hydrolysis leads to phenyl glycol. Iodohydrin is formed from styrene in the presence of iodine, mercury(II) oxide, and water. 1-Phenylethanol is an important intermediate product in the perfume industry (→ Flavors and Fragrances). It is formed by the hydration of styrene via quantitative addition of mercury(II) acetate:

The corresponding methyl ether is obtained by addition of methanol (e.g., at 135 – 150 °C in the presence of sulfuric acid):

Numerous reactions of styrene with sulfur and nitrogen compounds have been reported [3]. Thus, styrene reacts with sulfur dioxide, sulfur monochloride, sodium or ammonium dithionite, mercaptans, aniline, amines, diazomethane, and sodium hydrazide to give cleavage of the C=C double bond. Heating styrene with sulfur at high temperature gives hydrogen sulfide, styrene sulfide, and diphenylthiophenes.

Styrene sulfide

Styrene forms solid complexes with copper and silver salts at low temperature. These compounds are suitable for the purification of styrene, or for separating styrene from mixtures with other hydrocarbons. The color of the copper complexes makes this metal and its alloys unsuitable for use in contact with styrene.

Styrene also undergoes many cyclization reactions [7]; e.g.:

Lithium alkyls, such as C_2H_5Li, initiate a polymerization of styrene. In the presence of ethers, styrene is polymerized almost completely by sodium. Controlled polymerization (telomerization; →Organometallic Compounds and Homogeneous Catalysis, Chap. 3.2.4.) with olefins has generated a great deal of industrial interest, leading to new polymers that show promise as plasticizers, lubricants, and textile auxiliaries. Aromatic hydrocarbons such as benzene can be added to styrene in the presence

of aluminum chloride, just as they can to other olefins.

The high reactivity of the double bond, which is due to the resonance-stabilized aromatic ring, usually means that reactions must be carried out in several steps, with the double bond protected until the final step.

4. Production

Production of styrene is world-wide, and dates back more than 50 years. However, new variations on established processes are continually being developed, and new companies are building plants or buying out older producers. The feedstock for all commercial styrene manufacture is still ethylbenzene (→ Ethylbenzene). This is converted to a crude styrene that requires finishing to separate out the pure product.

4.1. Catalytic Dehydrogenation of Ethylbenzene

Direct dehydrogenation of ethylbenzene to styrene accounts for 85 % of commercial production. The reaction is carried out in the vapor phase with steam over a catalyst consisting primarily of iron oxide. The reaction is endothermic, and can be accomplished either adiabatically or isothermally. Both methods are used in practice.

4.1.1. Reaction Mechanisms

The major reaction is the reversible, endothermic conversion of ethylbenzene to styrene and hydrogen:

$$C_6H_5CH_2CH_3 \rightleftharpoons C_6H_5CH{=}CH_2 + H_2$$
$$\Delta H\,(600\,^\circ C) = 124.9\,\text{kJ/mol}$$

This reaction proceeds thermally with low yield and catalytically with high yield. As it is a reversible gas-phase reaction producing 2 mol of product from 1 mol of starting material, low pressure favors the forward reaction.

Competing thermal reactions degrade ethylbenzene to benzene, and also to carbon:

$$C_6H_5CH_2CH_3 \longrightarrow C_6H_6 + C_2H_4 \quad \Delta H = 101.8\,\text{kJ/mol}$$

$$C_6H_5CH_2CH_3 \longrightarrow 8\,C + 5\,H_2 \quad \Delta H = 1.72\,\text{kJ/mol}$$

Styrene also reacts catalytically to toluene:

$$C_6H_5CH{=}CH_2 + 2\,H_2 \longrightarrow C_6H_5CH_3 + CH_4$$

The problem with carbon production is that carbon is a catalyst poison. When potassium is incorporated into the iron oxide catalyst, the catalyst becomes self- cleaning (through enhancement of the reaction of carbon with steam to give carbon dioxide, which is removed in the reactor vent gas).

$$C + 2\,H_2O \longrightarrow CO_2 + 2\,H_2 \quad \Delta H = 99.6\,\text{kJ/mol}$$

Typical operating conditions in commercial reactors are ca. 620 °C and as low a pressure as practicable. The overall yield depends on the relative amounts of catalytic conversion to styrene and thermal cracking to byproducts. At equilibrium under typical conditions, the reversible reaction results in about 80 % conversion of ethylbenzene. However, the time and temperature necessary to achieve equilibrium give rise to excessive thermal cracking and reduced yield, so most commercial units operate at conversion levels of 50 – 70 wt %, with yields of 88 – 95 mol %.

Dehydrogenation of ethylbenzene is carried out in the presence of steam, which has a threefold role:

1) It lowers the partial pressure of ethylbenzene, shifting the equilibrium toward styrene and minimizing the loss to thermal cracking
2) It supplies the necessary heat of reaction
3) It cleans the catalyst by reacting with carbon to produce carbon dioxide and hydrogen.

Many catalysts have been described for this reaction [9]. One catalyst, Shell 105, dominated the market for many years, and was the first to include potassium as a promoter for the water-gas reaction. This catalyst is typically 84.3 % iron as Fe_2O_3, 2.4 % chromium as Cr_2O_3, and 13.3 %

potassium as K_2CO_3. It has good physical properties and good activity, and it gives fair yields [10].

More recently, increasing competition has promped manufacturers to seek new catalysts that produce higher yields without compromising activity or physical properties, or catalysts that meet specific requirements. The Süd-Chemie Group, which includes Nissan Girdler Catalyst in Japan, Süd-Chemie in Germany, and United Catalysts (UCI) in the United States, now has the major share of the catalyst market with its G-64 and G-84 types [11]. Shell also remains active through a joint partnership with American Cyanamid called Criterion Catalyst. In addition to Criterion 105, a series of new Criterion catalysts is available, including C-115 and C-025 HA. Dow Chemical and BASF manufacture their own catalysts to suit their specific needs, and there are other small producers as well. A catalyst life of ca. two years is claimed.

4.1.2. Adiabatic Dehydrogenation

Over 75 % of all operating styrene plants carry out the dehydrogenation reaction adiabatically in multiple reactors or reactor beds operated in series (Fig. 1). The necessary heat of reaction is applied at the inlet to each stage, either by injection of superheated steam or by indirect heat transfer.

Fresh ethylbenzene feed is mixed with recycled ethylbenzene and vaporized. Dilution steam must be added to prevent the ethylbenzene from forming coke. This stream is further heated by heat exchange, superheated steam is added to bring the system up to reaction temperature (ca. 640 °C), and the stream is passed through catalyst in the first reactor. Adiabatic reaction drops the temperature, so the outlet stream is reheated prior to passage through the second reactor. Conversion of ethylbenzene can vary with the system, but is often about 35 % in the first reactor and 65 % overall. The reactors are run at the lowest pressure that is safe and practicable. Some units operate under vacuum, while others operate at a low positive pressure. The steam: ethylbenzene ratio fed to the reactors is chosen to give optimum yield with minimum utility cost. The reactor effluent is fed through an efficient heat recovery system to minimize energy consumption, condensed, and separated into vent gas, a crude styrene hydrocarbon stream, and a steam condensate stream. The crude styrene goes to a distillation system. The steam condensate is steam-stripped, treated, and reused. The vent gas, mainly hydrogen and carbon dioxide, is treated to recover aromatics, after which it can be used as a fuel or a feed stream for chemical hydrogen. The complete technology is for sale from various licensors (Chap. 7).

4.1.3. Isothermal Dehydrogenation

Isothermal dehydrogenation (Fig. 2) was pioneered by BASF and has been used by them for many years. The reactor is built like a shell-and-tube heat exchanger. Ethylbenzene and steam flow through the tubes, which are packed with catalyst. The heat of reaction is supplied by hot flue gas on the shell side of the reactor – exchanger [12]. The steam : oil mass ratio can be lowered to about 1 : 1, and steam temperatures are lower than in the adiabatic process. A disadvantage is the practical size limitation on a reactor – exchanger, which restricts the size of a single-train plant to about 150×10^3 t/a, translating into increased capital for large plants.

Lurgi GmbH operates an isothermal reactor system that uses a molten salt mixture of sodium, lithium, and potassium carbonates as the heating medium. The multitubular reactor is operated at ca. 600 °C under vacuum and a steam : ethylbenzene ratio of 0.6 – 0.9. High conversion and selectivity are claimed [13]. A demonstration plant has been operated since 1985 at Mantova, Italy, by Montedison. The technology is offered for license by Lurgi, Montedison, and Deggendorfer, but so far no more units have been built.

4.1.4. Distillation of Crude Styrene

A typical crude styrene from the dehydrogenation process consists of:

Benzene (*bp* 80 °C)	1 %
Toluene (*bp* 110 °C)	2 %
Ethylbenzene (*bp* 136 °C)	32 %
Styrene (*bp* 145 °C)	64 %
Others	1 %

Figure 1. Adiabatic dehydrogenation of ethylbenzene (EB)

Figure 2. Isothermal dehydrogenation of ethylbenzene (EB)
a) Heater; b) Steam superheater; c) Reactor; d) Heat exchanger; e) Condenser

The separation of these components is reasonably straightforward, but residence time at elevated temperature needs to be minimized to reduce styrene polymerization. At least three steps are involved. Benzene and toluene are removed first, and either sent to a toluene dehydrogenation plant or further separated into benzene for recycling and toluene for sale. Ethylbenzene is then separated and recycled to the reactors. Finally, styrene is distilled away from the tars and polymers under vacuum to keep the temperature as low as possible. Figure 3 A shows a typical distillation train. The variant shown in Figure 3 B is the Monsanto approach, where the major split is accomplished first, followed by separation of the benzene – toluene mixture.

Figure 3. Distillation of crude styrene
A) Standard approach; B) Monsanto approach

Ethylbenzene and styrene, having similar boiling points, require 70 – 100 trays for their separation depending on the desired ethylbenzene content of the finished styrene. If bubble-cap trays are used, as in old plants, a large pressure drop over the trays means that two columns in series are necessary to keep reboiler temperatures low. Low-pressure drop trays, such as the Linde UCC sieve tray [14], permit this separation to be achieved in one column [15]. The most modern plants use packing in place of trays [16], [17]. This results in less pressure drop, giving a lower bottom temperature, shorter residence time, and hence less polymer (→ 12. Energy Management in Chemical Industry, Chap. 6.6., → 12. Energy Management in Chemical Industry, Chap. 7.). Sulzer has done pioneering work in the field of packings for distillation [18]. Koch, Norton, and Glitch also produce packings for this purpose.

A polymerization inhibitor (distillation inhibitor) is needed throughout the distillation

train. Sulfur was originally used, but environmental constraints make sulfur tar unacceptable as a fuel. Many new inhibitors have been marketed, usually aromatic compounds with amino, nitro, or hydroxy groups (e.g., phenylenediamines, dinitrophenols, and dinitrocresols). Uniroyal is especially active in this field. The distillation inhibitor tends to be colored and is thus unacceptable in the final product; finished monomer is usually inhibited instead with *tert*-butylcatechol (TBC) (10 – 50 mg/kg) during storage and transportation.

4.1.5. Oxidative Hydrogen Removal

Many efforts have been made to remove hydrogen from the process to favor the forward reaction. A new process is now being offered for licensing by Lummus, based on technology of UOP [19]. It employs a noble metal catalyst that selectively oxidizes hydrogen, allowing the ethylbenzene conversion to be increased to over 80 % while maintaining good styrene selectivity [20]. The process was originally named Styro-Plus, but is now called the SMART SM Process. It has performed well in a pilot unit (Mitsubishi Petrochemical, Japan) since 1985. It is mainly offered as a retrofit to existing units as a way of gaining extra capacity. It is claimed to have higher variable costs, but a lower capital cost than a conventional plant. Several licenses have been sold, but the corresponding plants are not yet operating.

4.2. Styrene – Propylene Oxide Process

The only other route to commercial production of styrene involves coproduction of propylene oxide, illustrated in simplified form in Fig. 4 [21] (→ Propylene Oxide, Chap. 4.2.). The first step is direct air oxidation of ethylbenzene at ca. 130 °C and 0.2 MPa. This gives ethylbenzene hydroperoxide (EBHP); α-methylbenzyl alcohol (MBA) and acetophenone (ACP) are also formed. Conversion is held to about 13 % in this step to minimize byproducts. The selectivity for ethylbenzene to EBHP is approximately 90 %, and the selectivity to MBA and ACP is 5 – 7 %.

$$C_6H_5C_2H_5 + O_2 \longrightarrow C_6H_5CH(OOH)CH_3 \text{ EBHP}$$

$$C_6H_5C_2H_5 + 1/2\,O_2 \longrightarrow C_6H_5CH(CH_3)OH \text{ MBA}$$

$$C_6H_5C_2H_5 + xO_2 \longrightarrow C_6H_5CO(CH_3) + \text{acids ACP}$$

Ethylbenzene hydroperoxide is then reacted with propylene in the presence of a metallic catalyst to form propylene oxide (PO) and more MBA. Liquid-phase molybdenum or heterogeneous titanium catalysts are used at ca. 110 °C and 4 MPa. The conversion of EBHP is nearly complete, with 70 – 85 % selectivity to PO and > 70 % selectivity to MBA.

$$C_6H_5CH(OOH)CH_3 + C_3H_6 \longrightarrow C_3H_6O + C_6H_5CH(CH_3)OH \text{ PO}$$

To improve yields, ACP is hydrogenated to MBA in the liquid phase at 90 – 150 °C and ca. 8 MPa. The catalyst is a mixture of ZnO and CuO. Approximately 90 % of the ACP is converted, with 92 % selectivity to MBA.

$$C_6H_5CO(CH_3) + H_2 \longrightarrow C_6H_5CH(CH_3)OH$$

Finally, the MBA is dehydrated to styrene at 250 °C and low pressure over a suitable metal oxide catalyst (often Al_2O_3).

$$C_6H_5CH(CH_3)OH \longrightarrow C_6H_5CH{=}CH_2 + H_2O$$

The patents issued to Halcon, Arco, and Shell on this process are extensive. The resulting ratio of styrene to PO is about 2.5. The process requires clean-up and purification steps to generate specification products.

The first commercial development of the process was by a joint venture company, Oxirane, formed by Halcon and Atlantic Richfield (ARCO); ARCO became the sole owner in 1980. Independently, Shell developed its own process based on similar chemistry. This route offers a way to manufacture propylene oxide without the need for chlorine as in the chlorohydrin process; (→ Propylene Oxide, Chap. 4.1.), but it is subject to market fluctuations in styrene and PO demand that do not match the stoichiometry of the process. The process requires a large capital investment and produces styrene at a higher cost than the conventional process, but credits for the coproduct PO can make the overall operation profitable. About 15 % of the world's supply of styrene is now made by this process.

Figure 4. Styrene – propylene oxide process
ACP acetophenone; EB ethylbenzene; EBHP ethylbenzene hydroperoxide; MBA methylbenzyl alcohol; PO propylene oxide; SM styrene monomer

4.3. Styrene from Butadiene

Another route to styrene that is being heavily researched starts with the Diels – Alder dimerization of 1,3-butadiene to 4-vinylcyclohexene-1 (VCH) [*100-40-3*] (→ Butadiene, Chap. 3.):

$$2\,C_4H_6 \longrightarrow C_6H_9CH{=}CH_2$$

This reaction is exothermic, and can be accomplished either thermally or catalytically. Thermal processes [22], [23] require a temperature of ca. 140 °C and a pressure of ca. 4 MPa. The thermal approach is most suitable for use with purified butadiene. Yields of VCH are ca. 90 %. The catalytic process is based on nitrosyl halide – iron complexes, and operates at 0 – 80 °C and 0.1 – 1.30 MPa [24], [25]. The yield is almost quantitative, and purification is not difficult. This route can accept either the raw C_4 stream from a naphtha or gas-oil steam cracker, or purified butadiene.

VCH is then dehydrogenated to ethylbenzene [26], [27] or, under more severe conditions, oxidatively dehydrogenated directly to styrene [28], [29]:

$$C_6H_9CH{=}CH_2 \longrightarrow C_6H_5CH_2CH_3 \longrightarrow C_6H_5CH{=}CH_2$$

This route to styrene is not yet economically attractive, but the availability and price of butadiene in the future could make it so.

4.4. Styrene from Toluene

There have been many attempts to find a route to styrene starting from toluene (→ Toluene). Toluene is readily available, is usually at least 15 % cheaper than benzene, and is not as toxic. However, no process has become commercially competitive. Monsanto worked extensively on a process for styrene starting with air oxidation of toluene to give stilbene [30]. This used a fluidized bed of supported lead oxide catalyst:

$$2\,C_6H_5CH_3 + O_2 \longrightarrow C_6H_5CH{=}CHC_6H_5 + H_2O$$
$$\Delta H = -\,77.26\ \mathrm{kJ\,g^{-1}\,mol^{-1}}$$

Stilbene is then reacted with ethylene over a molybdenum catalyst to give styrene:

$$C_6H_5CH{=}CHC_6H_5 + C_2H_4 \longrightarrow C_6H_5CH{=}CH_2$$
$$\Delta H = -\,15.99\ \mathrm{kJ\,g^{-1}\,mol^{-1}}$$

The idea attracted interest, but the project has been formally abandoned.

Another route being researched is the alkylation of toluene with methanol over zeolite catalysts [31–33]. The selectivity with respect to

toluene is claimed to be high, but it is only about 50 % based on methanol. No commercial plants have been announced.

4.5. Styrene from Pyrolysis Gasoline

An aromatic mixture ("pyrolysis gasoline;" → Benzene, Chap. 5.2.2.) including styrene is obtained from the thermal cracking of naptha or gas-oil. Recovery of the styrene has been proposed on the basis of extractive distillation with dimethylformamide or dimethylacetamide, by adsorption, by complex formation, or by membrane separation. So far none of these processes has been commercially exploited.

5. Quality and Testing

The specifications and methods of analysis for styrene have changed through the years. Almost all manufacturers use ASTM D 2827-92 in their sales specifications, which calls for a minimum purity of 99.7 %, but much of the styrene in today's competitive market is of much higher purity. Historically, styrene purity has been determined by freezing point, the method referred to in ASTM D 2827-92. Gas chromatography (GC) is used to determine specific impurities, and in practice, most manufacturers now use GC to determine overall purity by subtracting the total impurities from 100 %. Table 4 lists ASTM specifications and typical analysis for styrene monomer.

Table 4. ASTM styrene specifications (1993)

	ASTM D 2827-92	Typical analysis	ASTM method
Purity, %	99.7	99.8	D 3799*
Color, Pt – Co, max.	10	7	D 1209
Aldehydes, mg/kg	200	30	D 2119
Peroxides, mg/kg	100	5	D 2340
Polymer, mg/kg	10	0	D 2121
Inhibitor, mg/kg	10 – 15	12	D 4590
Impurities			D 5135**

* By freezing point.
** By gas chromatography.

The major impurities in styrene monomer are a function of the process variables. Ethylbenzene content varies depending on the effort put into the main ethylbenzene – styrene distillation column. α-Methylstyrene, isopropylbenzene (cumene), *n*-propylbenzene, and minor amounts of ethyltoluene and vinyltoluene in finished styrene are a function of the separation power of the styrene still. Xylene content is influenced by the purity of the feed ethylbenzene. Phenylacetylene is produced by the dehydrogenation process in amounts depending on the catalyst used, typically 50 – 150 mg/kg. Phenylacetylene must be removed by a hydrogenation step; it is absent from material made by the styrene – propylene oxide process.

6. Storage and Transportation

Styrene is a flammable, reactive monomer. It has a flash point of 31 °C and a flammable range of 1.1 – 6.1 vol % in air. It undergoes exothermic polymerization quite readily (0.02 %/h at 25 °C) liberating 69.8 kJ per mole of reacted monomer. Failure to remove this heat from an enclosed container could theoretically produce a temperature of 300 °C; uncontrolled polymerization may therefore lead to pressure build-up in a closed container, or a potentially explosive vapor cloud. However, styrene has been used on a large scale industrially for more than 50 years, and extensive experience is available with respect to preventive measures against fire and explosion, permitting problem-free storage and safe shipping of the monomer. Data are available from all styrene producers [5], [34].

Transportation of styrene monomer is subject to regulation in all countries (e.g., DOT in the United States and the VbF guidelines in Germany). The DOT identification number is UN 2055, and the reportable quantity for a spill is 454 kg.

Leakage can easily be detected owing to the characteristic styrene odor and a low odor threshold (0.005 mg/kg in air).

To increase its shelf life, styrene monomer is inhibited, typically with 4-*tert*-butylcatechol (TBC). Hydroquinone has also been used, but it is not as effective. At a TBC level of 12 mg/kg, a shelf life of 6 months is predicted at 20 °C; this falls to 3 months at 30 °C. This inhibitor requires trace amounts of oxygen to render it effective. To ensure a margin of safety, the recommended minimum oxygen level in the monomer

is 15 mg/kg. The solubility of oxygen from the air in styrene monomer is 50 mg/kg. To prevent the occurrence of hazardous polymerization, styrene should always be kept cool, and appropriate inhibitor and oxygen levels should be maintained.

Styrene in storage is frequently padded with inert gases, which are partially soluble in the monomer. The consequences of desorption of these gases must be considered in subsequent handling. When the oxygen level in the inert gas pad is < 8 vol %, the possibility of fire or explosion is eliminated.

Storage and shipping containers for styrene may be of standard steel or aluminum. Rust acts as a catalyst for the polymerization of styrene, so inorganic zinc linings are recommended for storage tanks. Copper and brass fittings must be avoided because they can lead to discoloration of the styrene. Contamination with bases must also be avoided, as these react with the inhibitor, making it ineffective. Loading on a common carrier in a compartment next to a heated product is an unacceptable practice.

Foam is the preferred medium for fighting styrene fires. Water fog dissipates vapor clouds and provides cooling for structural supports, but rarely extinguishes the fire. Styrene monomer, with its high volume resistivity, can acquire and hold a static electric charge during transfer. Effective grounding measures must therefore be taken to eliminate uncontrolled electric discharge.

7. Uses and Economic Aspects

Styrene monomer is used as a feedstock in a variety of polymer products: thermoplastics, elastomers, dispersions, and thermoset plastics. The following breakdown represents an estimate of the distribution of the monomer, as well as some of the uses of its derivatives [35].

Approximately 65 % of the styrene produced goes into polystyrene. This is used to make a wide range of products, from toys, housings for room air conditioners, and television cabinets, to cassettes, combs, and furniture parts. Polystyrene can also be foamed to produce insulation board, loose-fill packaging, and disposable food containers.

Approximately 6 % still goes into styrene – butadiene rubber elastomers (SBR) for such uses as passenger car tires, industrial hoses, and footwear.

Approximately 7 % goes to styrene – butadiene latexes, used in tufted carpet, paper coatings, and as a component in latex paints.

Approximately 9 % goes into styrene – acrylonitrile copolymer (SAN) and terpolymers of acrylonitrile, butadiene, and styrene (ABS) (→ Polystyrene and Styrene Copolymers); SAN is used for drinking tumblers and battery cases, ABS for piping, automotive components, refrigerator doorliners, and shower stalls.

A further 7 % is combined with unsaturated polyester resins in fiberglass-reinforced boats, storage tanks, shower units, and simulated marble products.

The remainder goes to miscellaneous uses, especially involving blends with other thermoplastics for a constantly growing line of products, including ion-exchange resins and adhesives.

World capacity for styrene in 1993 was estimated at ca. 17×10^6 t/a, in 1995 ca 18×10^6 t/a, divided among the most important markets as follows:

	1993	1995
North America	35 %	34 %
Western Europe	27 %	23 %
Japan	16 %	-
Korea	7 %	-
Far East (remainder)	5 %	-
Eastern Europe	5 %	6 %
South America	4 %	2.2 %
Middle East	1 %	3.3 %

Over 80 companies are now producing styrene monomer, but the pace of announcements of new plants, shutdown of old plants, and business mergers makes this a constantly changing number.

The majority of the producing companies have licensed their technology. A very rough estimate of capacities for the various technologies is as follows:

Badger	40 %
ABB Lummus Crest	24 %
PO/Styrene	13 %
Dow Chemical	11 %
BASF	7 %
Miscellaneous	5 %

Badger, a Raytheon Company, entered the styrene business in 1955. They acquired and developed portions of the Cosden, Union Carbide, and Fina styrene technology. Lummus Crest is part of the ABB group, and has acquired and developed the Monsanto styrene process, also merging technologies and resources with UOP and Unocal. ARCO and Shell own their own styrene – PO technologies. Dow and BASF have their own dehydrogenation technologies, and have both been making styrene for over 50 years. The size and age of the industry means that it is well reported and analyzed [34–36].

World-scale single-train units have a capacity of 450×10^3 t/a, but units down to 20×10^3 t/a still find their niche.

Benzene [*71-43-2*] (→ Benzene), used for making ethylbenzene, accounts for ca. 65 % of the cost of styrene. Large swings in the price of benzene are reflected in that of styrene, which also responds to variation in supply and demand. The price of styrene has fluctuated from a high of $ 1100/t in the late 1980s to $ 450/t in 1992 [37]. High profit margins tempt new producers into the business, and because they can buy their way in quickly via the licensors, overcapacity is easily reached (as in 1993), giving rise to a classic business cycle.

8. Related Monomers

Styrene can be substituted in the side chain or in the ring to give many other compounds; only the following have attracted commercial interest.

8.1. Vinyltoluene

Vinyltoluene, [*25013-15-4*] *p*-methylstyrene, $CH_3C_6H_4CH{=}CH_2$, is a specialty monomer, with properties similar to those of styrene [38]. It is available commercially in two different isomer mixes. For many years it has been supplied as a 68/32 mixture of the *meta* and *para* isomers, reflecting the composition of the feedstock ethyltoluene (ethylmethylbenzene), from the Friedel – Crafts synthesis (→ Hydrocarbons, Chap. 3.6.). This is usually called vinyltoluene (VT). The advent of a *para*-specific route to ethyltoluene using zeolite technology has made available a 97 % *para*-isomer product called PMS [*627-97-9*] to differentiate it from the original mix. The VT mix was originally developed to compete with styrene, with the idea that its feedstock (toluene) would give it a competitive advantage over a benzene-based material. However, benzene remained cheap and available, and VT proved to be more costly to make than styrene, so it has not gained a large market share. It has nevertheless maintained a specialty position because of its unique properties. Table 5 lists the physical properties of VT and PMS.

Table 5. Physical properties of VT and PMS

	VT	PMS
M_r	118.18	118.18
bp, °C	171.2	170.0
fp, °C	− 77	− 34
Flammable limits, vol % in air	1.1 – 5.2	
Flash point, TCC, °C	52.8	
Autoignition point, °C	575	
Heat of polymerization, ΔH_p, kJ/mol (25 °C)	− 70	− 70
Heat of vaporization, ΔH_v, J/g (25 °C)	426.1	410.9
Density, g/mL (25 °C)	0.8930	0.8920
Refractive index, n_D^{25}	1.5395	1.5408
Specific heat capacity (liquid), $J\,g^{-1}\,K^{-1}$ (20 °C)	1.715	
Viscosity, mPa s (25 °C)	0.79	0.79
Surface tension, mN/m (25 °C)	31.0	34.0
Solubility in water, mg/kg (25 °C)	90	

The reactivity of VT is similar to that of styrene. Thus, it undergoes both homopolymerization and copolymerization. Polymerization can be initiated by exposure to strong acids, peroxides, perchlorates, or hypochlorites. It also reacts similarly to styrene with oxygen and halogens, although the presence of an extra side chain makes the chemistry more complex.

The dehydrogenation of ethyltoluene to vinyltoluene is similar to that described for ethylbenzene to styrene. It is a vapor-phase process, employing superheated steam and a suitable catalyst. The amount of *o*-ethyltoluene in the feed should be kept at a minimum because it can form indene in the cracker, which impairs the properties of the final polymer. Distillation of the crude product must be performed carefully under vacuum to limit the temperature and thus the rate of polymerization. A suitable polymerization inhibitor is also necessary. The complexity of the crude reactor product requires elaborate separation by distillation to give a specification

product. The monomer is stored under refrigeration at 10 °C, and it is typically inhibited with TBC (12 mg/kg) during storage and transportation.

Toxicologically, VT has been considered to be very similar to styrene, and normal precautions should be taken when handling it (see Chap. 9). The ACGHI TLV is 50 mg/kg. VT is flammable, but its vapor pressure does not produce a flammable mixture in air below 38 °C. It polymerizes more rapidly than styrene, and polymerization can be initiated by exposure to strong acids, peroxides, perchlorates, or hypochlorites. Contact between vinyltoluene and a base will remove the TBC inhibitor.

Vinyltoluene is used in copolymers and as a specialty monomer in paint, varnish, and polyester formulations.

8.2. Divinylbenzene

Divinylbenzene (DVB) [*1321-74-0*], $C_6H_4(CH{=}CH_2)_2$, is a cross-linking agent that improves polymer properties. The commercial monomer is mainly a mixture of *m*- and *p*-DVB (typical ratio 2.25 : 1), diluted with ethylvinylbenzenes. Physical properties of the 55 % commercial mixture are listed below:

M_r	130.191
bp	195 °C
fp	−45 °C
Pseudocritical pressure	2.462 MPa
Pseudocritical temperature	369 °C
Flammable limits in air	0.8 – 5.5 vol %
Flash point, TCC	65.6 °C
Autoignition point	505 °C
Heat of vaporization, ΔH_v	
(195 °C)	350.6 J/g
Vapor pressure	
(100 °C)	4.4 kPa
(140 °C)	20.0 kPa
(180 °C)	67.0 kPa
Density (25 °C)	0.9084 g/mL
Refractive index, n_D^{25}	1.5585
Surface tension (25 °C)	32.1 mN/m
Viscosity (25 °C)	1.007 mPa s
Solubility	
DVB in water (25 °C)	0.0052 %
Water in DVB (25 °C)	0.054 %

The method of manufacture is analogous to that for styrene: endothermic dehydrogenation of an isomer mix of diethylbenzenes obtained as a side-stream of ethylbenzene production (→ Hydrocarbons, Chap. 3.4.). Diethylbenzene is vaporized, diluted with superheated steam, and then passed over a catalyst at ca. 600 °C. The reactor effluent is mainly *m*- and *p*-DVB, the corresponding ethylvinylbenzenes, and unreacted diethylbenzene. Most of the *o*-diethylbenzene undergoes ring closure to naphthalene. Separation of this mixture must compete with the ready polymerization of DVB. Separation can be achieved by vacuum distillation with suitable in-process polymerization inhibitors.

Divinylbenzene is more reactive than styrene, and can homopolymerize or copolymerize with many other monomers. Because of the two vinyl groups, the resulting polymers are cross-linked. Cross-linking improves solvent resistance, heat distortion, impact resistance, tensile strength, and hardness.

DVB is very similar to styrene monomer in its toxicological properties (Chap. 9). The ACGIH TLV for divinylbenzene is 10 mg/kg (53 mg/m^3). Its single-dose oral toxicity is low. Because DVB polymerizes so readily, additional precautions must be taken to prevent runaway reactions in storage. The monomer is inhibited with TBC (ca. 1000 mg/kg), and refrigerated storage at 10 °C is recommended.

Most DVB is used in ion-exchange resins based on suspension-polymerized beads of styrene – divinylbenzene. It is also used as a cross-linking agent in specialty rubber and other plastic applications (→ Polyester Resins, Unsaturated).

8.3. α-Methylstyrene

α-Methylstyrene (AMS) [*98-83-9*], $C_6H_5C(CH_3){=}CH_2$, is a monomer with a polymerization rate much lower than that of styrene. It can be produced commercially by the dehydrogenation of isopropylbenzene (cumene), but also occurs as a byproduct in the manufacture of phenol and acetone via the cumene oxidation process, now the major source of AMS (→ Acetone, Chap. 4.1.; →Hydrocarbons, Chap. 3.8.). Physical properties of AMS are listed below:

M_r	118.18
bp	165 °C
fp	−23.2 °C

Critical density	0.29 g/mL
Critical pressure	4.36 MPa
Critical temperature	384 °C
Critical volume	3.26 mL/g
Flammable limits in air	0.7 – 3.4 vol %
Flash point, Cleveland	
Open Cup (COC)	57.8 °C
Heat of polymerization	−39.75 kJ/mol
Heat of vaporization, ΔH_v	
(25 °C)	404.6 J/g
(165 °C)	326.4 J/g
Specific heat capacity (liquid)	
(20 °C)	2.047 J g^{-1} K^{-1}
(100 °C)	2.176 J g^{-1} K^{-1}
Specific heat capacity (vapor) (25 °C)	1.2357 J g^{-1} K^{-1},
Solubility	
AMS in water (25 °C)	0.056 %
water in AMS (25 °C)	0.010 %
Density (20 °C)	0.9106 g/mL
Viscosity (20 °C)	0.94 mPa s

AMS undergoes reactions and polymerizations similar to those of styrene and vinyltoluene. However, the addition of an α-methyl group to the side chain changes its chemical reactivity. AMS monomer tends to be more stable than other vinyl aromatics. Homopolymers are best prepared by ionic catalysis, copolymers by radical polymerization.

Toxicologically, AMS is similar to styrene (Chap. 9). The ACGIH TLV is 50 mg/kg, and the STEL 100 mg/kg. AMS has a higher flash point than styrene, and it is less likely to polymerize in storage. It forms low molecular mass polymers slowly after the depletion of oxygen and/or inhibitor. The polymer thus formed is usually a viscous liquid. Uninhibited AMS in storage oxidizes slowly to acetophenone, aldehydes, and peroxides, which may affect the polymerization rate.

Homopolymers of AMS are used as plasticizers in paints, waxes, and adhesives. The monomer is also used to form a copolymer with methyl methacrylate. The copolymer has a high heat-distortion temperature, and has been approved for use in food applications. Its light color makes it useful in modified polyester and alkyd resin formulations.

8.4. Chlorostyrene

The two compounds *ortho-* and *para-* chlorostyrene [*2039-87-4*], $ClC_6H_4CH{=}CH_2$, are reactive monomers produced only in small quantities. The *para* isomer has a boiling point of 192 °C and a flash point of 60 °C. It is combustible. Chlorostyrene is more reactive than styrene, and is easily polymerized. It is typically inhibited with 3,5-di-*tert*-butylcatechol (250 mg/kg) for storage and transportation.

The monomer can be manufactured from either *o-* or *p-* chloroethylbenzene by oxidation to the corresponding alcohol, followed by dehydration. It is possible to produce pure monomeric *o-* or *p-* chlorostyrene as well as a mixture of the two.

Extensive toxicological data for chlorostyrene are not available, but it is assumed to be similar to styrene (Chap. 9), with an ACGIH TWA of 50 mg/kg.

Chlorostyrene is used to provide shorter cure times, better heat-distortion properties, and flame resistance in polyester resins.

8.5. Vinylbenzyl Chloride

Vinylbenzyl chloride (VBC) [*30030-25-2*], $CH_2{=}CHC_6H_4CH_2Cl$, is also called (chloromethyl)ethenylbenzene or α- chloromethylstyrene. It is a difunctional monomer with both a polymerizable double bond and a benzylic chlorine, and is an isomeric mixture made by the chlorination of VT. VBC has a high boiling point (98.9 °C at 1.3 kPa) and low flammability. Other physical properties are as follows:

M_r	152.62
bp (1.33 kPa)	98.9 °C
(101.325 kPa)	229 °C∗
fp	−26 to −42 °C
Flash point, COC	104.4 °C
Autoignition point	610 – 620 °C
Heat of fusion, ΔH_m	−10.04 kJ/mol
Heat of vaporization, ΔH_v (157.2 °C)	334.0 J/g
Heat of polymerization, ΔH_p (195 °C)	−0.422 kJ/mol
Solubility in water (25 °C)	730 mg/kg

∗ Extrapolated value.

The reactivity of VBC is similar to that of VT. VBC is stored under refrigeration, and inhibited with 75 mg/kg of TBC and 800 mg/kg of nitromethane [38]. Its acute oral toxicity is claimed to be low, but the monomer vapor is a strong lachrymator. VBC can be transformed into a high molecular mass homopolymer, will copolymerize with many other monomers, and is used as comonomer in a variety of specialty plastics. It is also possible to carry out reactions

on the chloromethyl group, either before or after polymerization. The chemistry of VBC has been covered in an excellent review [39].

9. Toxicology and Occupational Health

In view of the large-volume production of styrene and the widespread use of styrene-based polymers in general, and especially in food-contact use, there is much research and a huge literature on the toxicology of styrene [40], [41] (→ Polyester Resins, Unsaturated, Chap. 9.).

Styrene is slightly toxic. In rats, the acute oral LD_{50} is 500 – 5000 mg/kg, with an inhalation $LC_{50} > 3000$ mg/kg. Death from acute dermal exposure has not been reported. Styrene is a moderate skin irritant, especially if trapped against the skin by contaminated clothing. Styrene vapor at high concentration has an irritant effect on the eyes and mucous membranes of humans and animals. Controlled observations on humans have shown that no irritation occurs at a concentration of ca. 100 mg/kg [42], [43], but trace amounts of styrene in the workplace together with trace amounts of halogen can produce a lachrymator in the presence of bright sunlight.

Styrene can affect the central nervous system, producing fatigue and headache at a certain level of exposure, and narcosis if the level is sufficiently high. Signs of transient impairment of central nervous system function have been described in voluntary test subjects [44] and in workers [45] exposed to styrene in concentrations of 375 –800 mg/kg. Impaired hearing and visual coordination have been detected after exposure to styrene at ca. 100 mg/kg. At 50 mg/kg, however, any negative effects of this type were considered doubtful or barely discernible [46]. Prenarcotic symptoms have been shown in workers exposed to a TWA of 50 mg/kg. They are clearly established at a TLV of 100 mg/kg [47].

A review of eight cohort studies involving nearly 50 000 employees over 46 years [48] showed no indication of human carcinogenicity related to styrene exposure. A comprehensive review of published data [49] concluded that there is little indication that styrene has any specific developmental or reproductive toxicity.

Long-term animal studies on styrene are more difficult to analyze. Limitations in the studies often preclude definitive conclusions. However, a review by Boyd et al. [50] concludes that there is no clear evidence of a carcinogenic response related to styrene exposure. It continues to be a problem to relate high-dose results in different animals to each other, and to project these to human response.

The metabolism of styrene proceeds through styrene-7,8-oxide to mandelic acid and phenylglyoxalic acid, which are then excreted in the urine [51]. There is a correlation in humans between urinary elimination of mandelic acid and the styrene concentration in the respiratory air if the latter is ≤ 100 mg/kg (420 mg/m^3). However, the styrene concentration in the blood seems to be a more reliable exposure index than either the mandelic acid content of urine or the styrene content in exhaled air.

The mouse seems to be a very sensitive species in styrene exposure studies. Mice apparently have a greater capacity than rats or humans to form styrene-7,8-oxide, and a lesser capacity to metabolize this chemical [52].

Nevertheless, the International Agency for Cancer Research classified styrene in 1987 as a possible human carcinogen, at the same time concluding that the evidence for carcinogenicity was limited, and in humans inadequate. This classification has provoked legislation, causing some countries and several states in the US to list styrene as a possible carcinogen. OSHA, on the other hand, decided in 1989 that styrene should not be regulated as a workplace carcinogen.

For styrene monomer, as for many other reactive substances, the toxic effect clearly depends on dose. Health risks can be expected at very high concentrations, but the no-observed-effect levels (NOEL) are considerably higher than those found in a well-managed operating facility, or in the background to which users of styrene-based products are exposed. The ACGIH TLVs for styrene are 50 mg/kg (213 mg/m^3) for an 8-h time-weighted average (TWA) exposure, with a 100 mg/kg (426 mg/m^3) short-term exposure limit (STEL), defined as a 15-min TWA [53]. The MAK value is 20 mL/m^3 (85 mg/m^3).

1. Terms, Distinguishing Criteria, Uses, Nutritional Physiology

The word sugars is the general term used in carbohydrate chemistry for all nutritive mono- and disaccharides such as glucose, fructose, galactose, maltose, and sucrose. Sugar is the technical and legal name for the disaccharide sucrose [*57-55-6*], (EINECS no. *200–334–9*). Irrespective of whether cane or beet is the source, the term sugar is used both in technology and in food laws. However, commercially a distinction is made between cane and beet sugar.

The chemical and physical properties of crystalline sugar made from cane and beet are largely identical. Slight differences exist only in the type and mass of the individual nonsugar substances that are enclosed in the sugar crystal or adsorbed on its surface (e.g., raffinose, theanderose [16], betaine, amino acids, potassium, sodium, calcium, or flavor- and taste-imparting substances). On the other hand, the $^{13}C/^{12}C$ abundance ratio (δ-^{13}C value) varies; it is ca. 11.3 ‰ for sucrose from cane and ca. 25.2 ‰ for sucrose from beet [17].

The origin of sucrose (i.e., cane or beet) can be determined unambiguously from this difference. It is attributed to the varying CO_2 fixation in the photosynthesis of sugarcane, a C_4 plant, and sugar beet, a C_3 plant [18]. However, a detection of unauthorized addition of cane white sugar to beet white sugar is limited by the variation of δ-^{13}C values.

Apart from the δ-^{13}C value, the δ-D/H and the δ-$^{18}O/^{16}O$ values are also gaining considerable importance as analytical determination tools, e.g., for detecting the unauthorized addition of sugar to fruit juice, honey, or wine (enrichment or chaptalization, after the French chemist F. Chaptal). With the help of these values, it is possible to assign a sugar sample to a definite area of cultivation. For instance, the addition of beet sugar from Michigan to orange juice from Florida, or the enrichment of must (wine) with beet sugar, can be detected unambiguously (Martin process) [19].

In the carbohydrate metabolism of the plant, sucrose plays an important role as the first nonphosphorylated compound. According to some calculations, plants synthesize 150×10^9 t of sucrose in one year as an intermediate product. In some juices from plant parts, the sucrose stored as a reserve substance accounts for up to 75 % of the solids. These plants serve as raw materials for the isolation of sugar. They are mainly sugar beet and sugarcane and, to a much lesser extent, dates [20] (Iraq, Iran, and the Near East), sweet corn [21] (Middle America), sweet sorghum [22] (Europe, North and South America), maple trees [23] (North America and Canada), and palms [24] (India).

Sugar is used predominantly in the production of food and beverages. The amounts added relative to the finished product vary considerably. They range from 70–80 % in hard boiled candies, to 40–50 % in chocolates and jams, ca. 20 % in cakes and pastries (pound cake, etc.), 10 % in carbonated beverages and soft drinks, and ca. 1 % in toast.

As a component of a formulation, sugar offers the following factors:

1) It confers sweetness on products and, after hydrolysis, participates in formation of the product-specific flavor and browning crust color (Maillard reaction, Strecker degradation, and caramelization) (→ Foods, 1. Survey)
2) It is a bulking (bodying) agent, which substantially influences the texture and mouth feeling of the products during consumption
3) Sugar is also important from a nutritional point of view

In some countries, sugar accounts for more than 10 % of the daily intake of calories (see Section 23, Table 18). Some nutritionists consider a sugar consumption of > 10 % of the daily intake of calories as too high. However, evaluation of the literature (e.g., for the U.S. FDA, United Kingdom, and Germany) has shown that except for the formation of caries, no scientific reasons exist for condemning a higher sugar consumption [25].

Sugar is used, for example, as a substrate for the production of ethanol (→ Ethanol, Chap. 5.1.1, → Ethanol, Chap. 5.1.2), citric acid (→ Citric Acid, Chap. 4.3), yeast (→ Yeasts), amino acids (→ Amino Acids), enzymes (→ Enzymes, Chap. 3.1), and antibiotics (→ Antibiotics, Chap. 5.4.2). For these biotechnological processes, sugar is often employed in the form of molasses (see Section 22.2). Sugar can be converted enzymatically to isomaltulose (→ Sugar Alcohols) and leucrose.

In Brazil, bioethanol is produced on a large scale from sugarcane raw juice (ca. 10×10^6 t/a) and used either directly as a carburetor fuel or as a gasoline–ethanol mixture (up to 20 vol % ethanol). The European Union supports the use of biofuels with the directives 2003/96/EC and 2003/30/EC. The target is to produce 5.75 % of the total fuel consumed in the EU from renewable energy sources by 2010 [26]. (→ Ethanol; → Automotive Fuels).

2. History [27]

Since time immemorial, man not only has craved salt but also had a desire for sweet food. Whereas the consumption of salt (electrolyte) is a physiological necessity, the desire for sweet food is associated with an adequate intake of calories. Sweet, naturally occurring products, such as mother's milk, honey, and fresh and dried fruits and their juices, not only are considered good and healthy, but also often have a high energy density.

Before humans were able to produce sugar from plants, honey and concentrated grape and fruit juices (which can be stored safely for a long time) were the sole sweeteners.

Rock drawings found in the Arana caves (eastern Spain, ca. 8000 B.C.) show how honey was collected from wild bees. Similar depictions of the collection of honey and the making of thickened grape must concentrates have been found in drawings in Egyptian tombs dating from 2600–1600 B.C.

2.1. Development of the Cane Sugar Industry

On the Indian subcontinent, the practice of chewing and sucking bits of cane was popular in early days. According to recent research, sugarcane has been cultivated in New Guinea since 8000 B.C. It traveled from there to Indochina,

Table 1. Main beet and cane sugar producing countries (2002–2003) [28]

Beet sugar	Raw sugar, 10^3 t	Cane sugar	Raw sugar, 10^3 t
France	5140

and finally, to the Bay of Bengal, where it was crossed with native wild species in India.

Much later, about 5000 B.C., a sugar syrup was prepared by pressing or boiling cane and thickening the juice. This type of sugar production was practiced for thousands of years. The art of producing solid sugar from cane was developed in India about A.D. 200–400.

Through the campaigns of Alexander the Great in India (327 B.C.), information about sugarcane first reached Europe.

The cultivation of sugarcane spread from India to China (200 B.C.) and Java, as well as to Sicily and Spain via Persia and lower Egypt. The Egyptians had a developed sugarcane industry as early as A.D. 1000 and became the masters of their former teachers, China, Persia, and India. However, the sugarcane cultures in Syria, Egypt, and Cyprus were, for the most part, destroyed by the Turkish campaigns in the 15th century. The Portuguese Prince Henry the Seafarer transplanted sugarcane from Sicily to Madeira in 1420 and laid the foundations for a flourishing industry on the Canary Islands. On his second voyage in 1493, Christopher Columbus brought sugarcane from the Canaries to Hispaniola, which was later called Santo Domingo. Thus, the foundations were laid for the powerful sugarcane industry of the West Indian Antilles, the sugar islands, which supplied the European market for centuries. Sugarcane then traveled via Middle America to South and North America and to almost all tropical and subtropical regions.

Since the cultivation of sugarcane is very labor intensive, a flourishing slave trade had developed between Africa and America by the beginning of the 16th century. This trade brought with it social, political, and economic problems that finally led to the abolition of slavery in the second half of the 19th century.

Sugarcane was introduced into Europe in A.D. 996. As a result of the spread of trade relations to the Arab countries and, above all, the Crusades (1096–1291), sugar quickly became known and appreciated as both a medicine and a luxury article. The European sugar trade was controlled almost exclusively by the Republic of Venice. With the decline of Venice after the Thirty Years' War, the sugar trade was taken over by Holland and, later, by England.

The main cane sugar producing countries are listed in Table 1. In Europe, sugarcane is cultivated only in Spain.

2.2. Development of the Beet Sugar Industry

While studying the isolation of sugar from native plants in Berlin, Andreas Sigismund Marggraf (1709–1782) discovered in 1747 that the sugar present in beet root is chemically identical to cane sugar. He also isolated D-glucose (dextrose, grape sugar) from grape juice (→ Glucose and Glucose-Containing Syrups, Chap. 1). Publication of this important discovery laid the foundation for the European beet sugar industry. Marggraf also indicated how sugar could be isolated from beet and recognized the economic

importance of this branch of industry. However, his discovery remained virtually unused in his lifetime.

Franz Carl Achard (1753–1821) recognized that a beet with a high sugar content is necessary for economic sugar production.

Achard developed selection–breeding methods that are still valid. In addition, he perfected the technology of sugar isolation and, after overcoming many difficulties, was able to present the first sample of beet sugar to the Prussian king Friedrich Wilhelm III on January 11, 1799. In 1801 a sugar factory was built in Kunern, and it was put into operation in April 1802. After completing his campaign, Achard described his experiences in a paper published by Wilhelm Gottlieb Korn, "Instructions for the Cultivation of Beet Used in Sugar Production and for the Profitable Isolation of Sugar from Beet," which appeared in Breslau in 1803. However, the expected economic success failed to materialize. The factory burned down in 1807 and was not rebuilt [29].

Table 2. Solubility of sucrose in pure water under normal pressure, according to [34] *

t, °C	S, wt %	L_t
0	64.45	1.8127
10	65.43	1.8926
20	66.72	2.0047
30	68.29	2.1535
40	70.10	2.3450
50	72.12	2.5863
60	74.26	2.8857
70	76.48	3.2515
80	78.68	3.6901
90	80.77	4.2003
100	82.65	4.7637

* As calculated from the equation
$S = 64.447 + 8.222 \cdot 10^{-2} t + 1.6169 \cdot 10^{-3} t^2 - 1.558 \cdot 10^{-6} t^3 - 4.63 \cdot 10^{-8} t^4$. S = weight percent of sucrose, L_t = g sucrose per g water.

As a result of the continental blockade imposed by Napoleon on England in 1806 and delivery problems for the cane sugar industry resulting from the slave rebellions of 1791, some sugar factories were set up in Germany and France. However, most of them had to be closed down after a short time because they did not operate profitably. The French sugar industry fared better because it was strongly supported by Napoleon. Only the sugar factories founded after 1831 endured. The Zuckerfabrik Waghäusel/Baden of Südzucker AG, founded in 1837, was operated during a period of nearly 160 years, until 1994, and was the oldest beet sugar factory in the world in operation at the end of the 20th century.

The main beet producing countries are listed in Table 1. In the United States, the People's Republic of China, Spain, Pakistan, Japan, and Uruguay, sugarcane and sugar beet are cultivated side by side. As compared with 1990, the fraction of beet sugar declined from 38 % to 25 % of the total production and a further drop is to be expected in the future (see Section 23).

3. Properties

The conformation of crystalline sucrose is shown in Figure 1. The glucose portion has the $^4C_1$ chair form (→ Glucose and Glucose-Containing Syrups), and the fructose portion the $^4T_3$ twist conformation (→ Fructose, Chap. 2.1). The two rings are almost at right angles to each other. Strong intramolecular hydrogen bonds exist between the 6′-OH group of fructofuranose and the ring oxygen of glucopyranose (189 pm) and between the 1′-OH of fructose and the 2-O of the glucose moiety (185 pm). Since the two glycosidic hydroxyl groups are linked in etherlike fashion to each other, α-1 → β-2, sucrose is a nonreducing disaccharide.

Figure 1. Conformation of sucrose

The specific rotation of sucrose in water is $[\alpha]_D^{20}$ =+ 66.529° [12] (measured at a concentration of 26 g filled to 100 cm^3 with water, but recalculated to c = 1 g/cm^3 and 1 dm of optical path length).

Table 3. Density of aqueous sucrose solutions (in g/cm^3), according to [35]

* Values extrapolated below the temperature range of the measurements.

The IR spectrum of sucrose exhibits characteristically sharp bands at 1010, 990, 940, 920, 870, and 850 cm^{-1} and wide bands at 680 and 580 cm^{-1}.

3.1. Physical Properties of Crystalline Sugar

At 0–95 °C, sucrose forms monoclinic anhydrous crystals that have an axial ratio of 1.2532 : 1 : 0.8895; 103° [30]. The *crystallization enthalpy* is 360 J/mol, and the *density* is 1.5879 g/cm^3 at 15 °C and 1.5871 g/cm^3 at 20 °C [31].

Sugar crystals of different morphology and shapes are formed, depending on the conditions of crystallization and the nonsugars inserted in the crystal lattice. Hence, commercially crystallized sugar occurs in many crystal forms [32].

The *melting point* of pure sucrose is 186 °C; commercially available sugar melts in the range 175–190 °C, depending on purity.

On heating a sugar melt (5–20 min) to 180–210 °C, the disaccharide bond is cleaved and the resulting monosaccharides eliminate water to yield volatile and nonvolatile aroma imparting substances, such as 2-butanone [*78-93-3*], 2-acetofuran, furanone, 5-(hydroxymethyl)furfural [*67-47-0*], levoglucosan [*498-07-7*], levoglucosone [*37112-31-5*], anhydroglucoses [*498-07-7*], difructose anhydrides [*124277-48-1*], and polymers of these monomers. The product is known as burnt sugar.

When heated above 250 °C, the carbon chain is increasingly broken up to yield small gaseous molecules, such as CO_2 and H_2, the residue remaining is sugar charcoal.

3.2. Physical Properties of Aqueous Sugar Solutions

When sucrose is dissolved in water, the three primary hydroxyl groups are hydrated first with the formation of hydrogen bonds, followed by the secondary hydroxyl groups. Up to a mass concentration of about 67 % at 25 °C, sugar molecules are hydrated with water molecules in the form of clusters [33]. For this reason, sugar is readily soluble in water. The pH of sugar solutions is 5.0–8.0. The pK values at 25 °C are pK_1 = 12.7 and pK_2 = 13.1.

At higher concentration, sugar forms viscous syrups that are easily supersaturated. Their rate of crystallization is influenced by the type and quantity of impurities present in the solution (see Fig. 8). The solubility of pure sucrose in water as a function of temperature is given in Table 2

[34]. The density of aqueous sucrose solutions as a function of concentration and temperature is listed in Table 3 [35]. Viscosity is important for the industrial processing of sucrose solutions (see Table 4) [36]. It increases with increasing concentration ($\eta = A \cdot 10 \cdot Bb/100 - b$) and decreases with increasing temperature ($\eta = A \cdot B/T$, where A and B are constants, T is the absolute temperature, and b is the solids content).

The most important physical properties of sugar and sugar solutions are summarized in [37].

3.3. Chemical Properties

As a result of the labile furan ring in the fructose portion of the molecule, sucrose can be cleaved easily into its components by hydrogen activation or enzymes. This reaction proceeds with a gain in energy (− 27.9 kJ/mol). The dextrorotatory labile β-fructofuranose released at first is rearranged quickly to give the levorotatory tautomeric mixture (→ Fructose). This is a first-order reaction. Thus, the resulting mixture of equal parts of glucose and fructose becomes levorotatory $[\alpha]_{\mathrm{D}}^{20} = -22.2°$ and is called invert sugar. The cleavage reaction is known as the inversion of sucrose.

Sucrose can be cleaved from both the fructosidic (β-fructosidases, invertase) and the glucosidic (α-glucosidases, sucrases) sides. Microorganisms are capable to produce both enzymes. Cleavage by β-fructosidases predominates in plants and cleavage by α-glucosidases in animals. The latter also applies to the enzyme system of the human mucosa. Because sucrose, being a disaccharide, cannot pass through the intestinal wall, its enzymatic cleavage is a requirement for the absorption and metabolism of sucrose.

In *food production*, the processing parameters (pH, temperature, residence time) are optimized so that the amount of invert sugar produced is just enough for the flavor and browning (color).

With acidic food and drink, attention must be paid to the fact that only traces of hydroxymethylfurfural (HMF) are formed from the fructose part of the molecule (→ Fructose, Chap. 2.3).

In the alkaline degradation of sugar during juice purification, the invert sugar present in sugar beet is degraded to organic acids (D- and L-lactic acid, acetic acid, formic acid, and saccharinic acid). Alternatively, juice purification can be carried out in such a way that the invert sugar is not broken down (cane sugar juice purification).

3.4. Sensory Properties

The sweetness of aqueous sucrose solutions is set as the standard (= 1) and is used by way of comparison to determine the relative sweetness of other substances. The intensity of sweetness of food and beverages depends on sugar concentration, temperature, and the matrix of the food (viscosity in the case of solutions and texture in the case of pasty, solid foods).

The taste profile of sugar is purely sweet and free from all secondary tastes. As with the sweetness, the course of the intensity–time curve of sucrose solution, an important characteristic for the sensation of sweetness, is used as the standard for the determination of curves of this type for other sweetening agents [38].

4. Sucrochemistry, Chemical and Enzymatic Synthesis

4.1. Sucrochemistry

Since the middle of the last century, the world's sugar production has increased greatly (Chap. 23, Table 17) and is consistently higher than the requirements of traditional markets. Furthermore, the production of sugar could be increased still further; sugar is produced in a highly pure state and is one of the cheapest bulk organic chemicals. For all of these reasons, attempts have been made since 1948 to use sugar as a raw material for chemical syntheses.

With the oil crisis in the mid-1970s, these efforts were given a strong impetus by the general realization of the limited availability of fossil fuels. Sugar presented itself as an easily renewable energy resource (see also → Fructose, Chap. 2.3). This area of sucrose chemistry was given the name "sucrochemistry." The numerous microbiological transformation products of

sucrose are not included in the field of sucrochemistry.

Processes for the use of sucrose [39] or other compounds, which are obtainable from the skeletal substances of beet and cane, as chemical raw materials can be divided into three groups:

1) Direct chemical conversion of the unchanged sucrose molecule
2) Chemical conversion of compounds made from sugar (e.g., glucose, fructose, isomaltulose, leucrose, isomalt, hydroxymethylfurfural)
3) Use of side products of sugar processing for the production of bulk chemicals, e.g., xylose or furfural (→ Furfural and Derivatives, Chap. 3) from bagasse, L-araban, L-arabinose, and pectin from beet cossettes

Extracted beet cossettes are used as substrates in solid fermentation to produce protein-enriched cossettes [protein content 19–24 % of dry substance (DS)] [40], and enzymes, such as pectinases and other hydrolases [41].

Apart from esters with fatty acids (e.g., for the production of biologically degradable surfactants and ethers), sugars or products belonging to the second group are oxidized to carboxylic acids, reduced to alcohols, or subjected to destructive hydrogenation and reductive amination.

In summary, sucrochemistry has not gained much success until now although it includes interesting compounds, e.g., 4,1′,6′-trichloro-4,1′,6′-trideoxygalactosucrose [*56038-13-2*], which is suitable as an intense sweetener.

4.2. Chemical and Enzymatic Synthesis

Despite its great economic importance, attempts to synthesize sucrose were made relatively late. In 1928, the tetraacetates of glucopyranose and fructofuranose with free glycosidic groups were chemically linked by the addition of dehydrating agents [42]. However, the resulting octaacetates did not have the proper steric conformation of sucrose (α-1 → β-2) but were the acetates of the isomeric isosucrose [43].

The first successful chemical synthesis of sucrose involved the condensation of 1,2-anhydro-3,4,6-tri-*O*-acetyl-D-glucopyranose (Brigl's anhydride) with syrupy 1,3,4,6-tetra-*O*-acetyl-D-fructofuranose, followed by deacylation. The synthesis could be improved by using crystallized 1,3,4,6-tetra-*O*-benzyl-D-fructofuranose (instead of the syrupy tetra-*O*-acetyl compound), but here too the yield of sucrose was only ca. 35 % [44].

A successful biochemical synthesis [45] used a bacterial phosphorylase (EC 2.4.1.7), which catalyzed the following reaction:

α-D-glucose 1-phosphate + D-fructose $\rightleftarrows$ sucrose + phosphate

In this way, sucrose could be prepared in the crystalline state [46]. However, the reaction equilibrium favors cleavage, reflecting the physiological significance of sucrose phosphorylase (degradation reaction).

4.3. Plant Biosynthesis

In plants, the biosynthesis of sucrose occurs in the cytosol (especially of the leaves) from the "active" forms of glucose and fructose: uridine diphosphate (UDP) glucose and fructose 6-phosphate. These two compounds are, in turn, formed from the triose phosphates produced directly in the Calvin cycle [47]:

Triose phosphate → fructose 1,6-diphosphate → glucose 6-phosphate → glucose 1-phosphate

The actual synthesis of sucrose proceeds via three enzymatic steps:

Glucose 1-phosphate + UTP
$\rightleftarrows$ UDP-glucose + PP (1)

UDP-glucose + fructose 6-phosphate
$\rightleftarrows$ sucrose 6^F-phosphate + UDP (2)

Sucrose 6^F-phosphate + H_2O
$\rightleftarrows$ sucrose + P (3)

Enzymes:
Reaction (1): UDP-glucose pyrophosphorylase (EC 2.7.7.9)
Reaction (2): Sucrose-phosphate synthase (EC 2.4.1.14)
Reaction (3): Sucrose phosphatase (EC 3.1.3.2.24)

With the cleavage of the pyrophosphate (PP) formed in reaction 1, three energy-rich phosphate bonds are hydrolyzed in the synthesis of sucrose. Hence, the equilibrium favors formation of sucrose.

At the time of storage, sucrose is transported in an energy-dependent process from the epigeal parts of the plant (source) through the phloem and into the roots [48]. The storage parenchymal cells (sink), in turn, concentrate sucrose within the tonoplasts in an energy-dependent process. Thus, the source–sink relationship and the osmotic conditions are retained [18, 49].

The assimilation efficiency in sugarcane was studied with labeled $^{14}CO_2$. C. E. Hartt [50] found that 65 % of the carbon dioxide absorbed is used for the synthesis of sucrose and that a single leaf of about 5.7 dm^2 produces 100 mg of sucrose in 1 h. Of these 100 mg, 74 mg is transported to the stalk for storage. A large plant possesses about 22 leaves with a total area of 122 dm^2, which corresponds to a sucrose production of 2.140 g/h.

5. Methods of Analysis

In the analytical methods applied in the sugar factory, a distinction is made between methods for

1) *Final product control,* which are largely stipulated in international agreements (WHO–FAO Codex Commission, pharmacopoeias, etc.) and in national food and feed regulations.
2) *In-process control,* which must be simple but easily reproducible because of the large number of analyses to be performed. For this purpose, optical methods, polarimetry, and refractometry have gained acceptance.

At first, quartz wedge compensation instruments were used exclusively as polarimeters. They were calibrated to give a rotation of 100 (100° Ventzke), corresponding to 34.657 radians, for a solution of 26.00 g of pure sucrose, weighed in air, made up to 100 cm^3 with water, and measured with sodium light (D lines) at 20 °C in a 2-dm tube. The instruments were checked with calibrated quartz plates because quartz and sucrose have about the same rotatory dispersion at wavelengths close to the D lines. With 26 g of substance per 100 cm^3, the percentage of sucrose in the sugar solution is obtained directly from the angle of rotation in degrees Ventzke. Later 100° S (International Sugar Degrees) was used, corresponding to 34.616 radians for the yellow sodium lines of 589.44 nm [51]. Lead acetate solutions were used to clarify the solution. For environmental reasons, clarification is achieved today with aluminum–zinc salts with sodium or calcium hydroxide solutions. As a further alternative to lead acetate clarification, polarimeters are being used that work in the near-infrared range, to permit a measurement of unclarified, dark solutions directly after dilution.

More recent measurements with highly purified sucrose showed certain deviations from the old scale. Thus, the hundred-degree points for various wavelengths were redetermined so that further development of instrumentation would not be hindered [52]. The hundred-degree point for the mercury isotope line ^{198}Hg is:

$$\alpha \frac{20.00^\circ\mathrm{C}}{546.2271\,\mathrm{nm}} = 40.777^\circ \pm 0.001^\circ$$

for the yellow sodium lines:

$$\alpha \frac{20.00^\circ\mathrm{C}}{589.4400\,\mathrm{nm}} = 34.626^\circ \pm 0.001^\circ$$

for the helium–neon laser:

$$\alpha \frac{20.00^\circ\mathrm{C}}{632.9914\,\mathrm{nm}} = 29.751^\circ \pm 0.001^\circ$$

for near-infrared wavelengths:

$$\alpha^{20.00^\circ\mathrm{C}}_{882.60\,\mathrm{nm}} = 14.836^\circ \pm 0.001^\circ$$

$$\alpha^{20.00^\circ\mathrm{C}}_{880.00\,\mathrm{nm}} = 14.927^\circ \pm 0.001^\circ$$

and is defined as 100°Z in the sugar polarimeter.

Another important method is determination of the solids content of juices, syrups, and crystal magmas (massecuite). In the beet sugar industry this is determined almost exclusively from the refractive index of the solutions. The refractive indices of pure sucrose solutions have been determined with great accuracy and are internationally defined [53].

Errors made in using the refractive index for determination of the solids content of impure sugar solutions increase as the nonsugar portion increases. For molasses, these errors are of the order of 1–3 % absolute, compared to values obtained by determining the water content of molasses with Karl Fischer reagent solutions (→ Gas Production, Chap. 8.2.2.3). Nevertheless, the accuracy of the refractometric method is sufficient for technical purposes.

The degree of purity p (or simply purity) is an important value in controlling the success of technological measures. Determined from the polarization, p gives the sucrose content as a percentage of the total solids content. In the raw juice obtained by extracting sugar beet, sucrose accounts for about 90 % of the solids content (i.e., the purity of raw juice is 90 %); the purity of thick juices is approximately 92 % and that of molasses ca. 60 %. This type of purity determination gives approximately correct results only in the case of intermediates in sugar beet processing. It cannot be applied to cane products because the polarimetric determination of sucrose gives incorrect results owing to the high content of invert sugar in these products. In these cases, modern analytical methods for saccharides (GC, HPLC, ion chromatography) must be used to determine the actual sucrose concentration in the products.

In the making of sugar, other important methods of analysis involve the determination of color, inorganic constituents (ash), and individual nonsucrose organics, e.g., glucose and fructose (invert sugar), raffinose, D- and L-lactic acid, citric acid, amino acids, betaine. Lately, enzymatic and chromatographic methods [GC, high-performance ion-exchange chromatography (HPIC), HPLC, high-performance anion-exchange chromatography (HPAEC)] for the determination of organic nonsugar substances have gained acceptance.

The International Commission for Uniform Methods of Sugar Analysis (ICUMSA http://www.icumsa.org), founded in 1897, meets once every four years (since 2002 biennially) to solve analytical problems on an international level. The results of these meetings are published in the Commission's proceedings (last issues: 1990, 1994, 1998, 2002, 2004). Methods for the analytical control of final and intermediate products that are accepted by ICUMSA were summarized in monographs in the past [54] and are published in the loose-leaf ICUMSA Methods Book today [55].

In addition to laboratory methods, on-line measurements of, e.g., dry substance (measured by refraction), white sugar color, pulp moisture, juice alkalinity, and juice hardness are gaining in importance.

6. Sugar Beets: Cultivation, Harvesting, Preparation

6.1. Cultivation [56]

The sugar beet, *Beta vulgaris altissima,* is a biennial plant that is, however, harvested after the first vegetation period for the production of sugar. At that time, the largest amount of sugar is stored in the fleshy root. Thus, the sugar beet is processed before it reaches physiological maturity.

The sugar beet grown today was bred by Achard from the "white Silesian beet" by means of selection. The wild beet *Beta maritima* L., still found in the coastal areas of the Mediterranean and the Atlantic, is regarded as the original form of sugar beet. Like other plants belonging to this genus (fodder beet, beetroot, and chard), the sugar beet has 2×9 chromosomes (i.e., it is diploid).

Classical breeding was based on individual selection, in which the quality of the mother plant was judged on the basis of the properties of the progeny (surface appearance, density of roots, sugar content of cell sap, etc.). The development of a new variety took 16–20 years. New breeds were largely impaired because of self-sterility and the resulting difficulty in inbreeding. A considerable step forward was achieved around 1950 with the introduction of hybrid breeding by the use of sterile male plants. Thus, inbred lines could be developed and crossed. Introduction of the haploid technique has made breeding easier. In this technique, plants are regenerated from unfertilized germ cells. These plants are 100 % homozygous after the doubling of their set of chromosomes. Consequently, in the breeding of sugar beet, improvements in quality can now be achieved much faster. With the help of genetic engineering [57], efforts have been made to make sugar beets resistant to viral diseases (e.g. Rhizomania A, B, and P types, caused by the virus BNYVV and transmitted by the fungus *Polymyxa betae*) and to herbicides, as well as to changes in the concentration of sugar or other constituents (raffinose, betaine, etc.). From the 1970s to 2000 breeding of Rhizomania resistent varieties with normal sugar yield was a very important goal and the success was a milestone in sugar beet breeding. Concepts to

develop Rhizoctonia solani resistance in a similar way are just at the beginning, and the first resistant variety was registered in 2001 [58].

Genetically monogerminal seeds are usually sown in pellet form. Fungicides and insecticides are contained in the cover mass so that further plant protection measures, with the exception of herbicide treatment, are not required during growth.

Efforts are made to achieve a plant population of 80 000–120 000/ha, depending on climatic conditions (row width is 38–50 cm; space between plants in a row is 18–22 cm in the case of cultivation without thinning and 12 cm in the case of mechanical thinning to give a desired number of plants per hectare after germination of the seeds). With the introduction of genetically monogerminal seeds, the labor expended (working hours) in sowing sugar beet was reduced from about 45 h (cultivation with thinning) to 3–11 h for cultivation without thinning, depending on the size of the field (0.5–5 ha). The total amount of labor (including preparation of the field, harvesting, and loading of the beets) decreased to the same extent. In fact, the working hours per hectare were reduced from 260 h in 1967 to 15–50 h, depending on the size of the fields and the harvesting technique used (e.g., a six-row self-propelled combine harvester). The harvesting process, subsequent mechanical removal of dirt tare, and the loading of beets must be conducted gently so that mechanical damage to the beets is as low as possible (< 600 cm^2 per 100 beets). With mechanically damaged beets, high sugar losses occur during storage, washing, and fluming. For undamaged beets sugar losses at this stage are typically 0.3–0.5 %, but for damaged beets ca. 1 %.

In Central Europe and the United States, the vegetation period is about 170–200 days (April 1 to October 15). The time required between sowing and germination is 22 days. In the case of a winter rainfall of 240 mm, the amount of precipitation during the vegetation period should be at least 360 mm. The total heat (sum of the average daytime temperatures during the vegetation period) required to ripen sugar beet is 2500–2900, with the longest possible duration of sunshine in the months of July to September.

The nutrient withdrawal per hectare for 10 t of beets including the leaves is 45 kg of nitrogen, 6 kg of phosphorus, 52 kg of potassium, 15 kg of sodium, 16 kg of calcium, and 8 kg of magnesium. Depending on the fertilization state of the soil (→ Fertilizers, Chap. 2.3.2), fertilization with 120–160 kg of nitrogen, 80–130 kg of P_2O_5, and 150–250 kg of K_2O per hectare compensates for deficiencies. In organic fertilization with farmyard manure, liquid manure, or straw, the mineral components present should also be taken into account. For fertilization, the ratio of N : P : K must be about 1 : 0.4 : 1, based on the pure nutrients, to make sure that the plant has a balanced supply of nutrients. Since the late 1980s, the beet yield (return) per hectare in Western Europe has been an average of 50.8 t, with large regional variations (e.g., Finland 29.2 t/ha, Switzerland 60.3 t/ha). The yield in the United States is somewhat lower, and that in the Commonwealth of Independent States and other Eastern European countries is only two-thirds of this amount.

Since the sugar concentration in beet does not vary greatly (18.4 % in Austria, 13.9 % in Greece), the mass of white sugar produced per hectare correlates with the beet yield per hectare. This is ca. 7.47 t/ha in Western Europe (Finland 4.20, Switzerland 9.06), 6.5 t in the United States, and 4 t/ha in Eastern European countries.

Together with the tops (yield of ca. 20–40 t/ha), which constitute a valuable feed after silage, the utilizable energy obtained per hectare of a sugar beet field is 219 GJ (100 %), compared with 89 GJ/ha for the cultivation of potatoes (40 %), 69 GJ/ha for wheat (31 %), and 114 GJ/ha for the cultivation of grain corn (52 %).

In most areas under cultivation, sugar beet is cut back when harvested. In Europe, for example, the leaves and the beet crown (ca. 15 % of the mass of the defoliated root) are separated from the root body. In the United States, the crown part that is cut off is much smaller (≈ 6 %). Despite the use of considerable mechanization in sowing, care, and harvesting, and of herbicides, fungicides, and insecticides, the cultivation of sugar beet is still one of the most labor intensive areas in agriculture.

6.2. Chemical Composition and Beet Quality

Even beets that are harvested from the same field do not represent homogeneous material. There-

Figure 2. Average chemical composition of sugar beet

fore, data on the chemical composition of sugar beets (Fig. 2) should always be regarded as average values for normally grown beets. Also, certain criteria must be maintained as far as sampling and the size of random samples are concerned [59].

The root body consists of about 75–78 % water. Of its solids (22–25 %), sugar (sucrose) accounts for 15–18 %, raw protein 1–1.2 % (total N×6.25), raw fat 0.1 %, raw fiber 1.1–1.3 %, pectinous substances 1.0–1.2 %, nitrogen-free extractive substances (apart from sucrose) 2.8–3.0 %, and inorganic components 0.7–0.9 %. Similar figures were given in a monograph in 1998 [1]. In sugar technology, sugar beets are subdivided more usefully into "marc" and "cell juice." The marc, which accounts for ca. 4–5.5 % of the sugar beet mass, refers to the components that are insoluble in water under certain extraction conditions (i.e., beet skeletal substances consisting of cellulose, lignin, pectin, araban, and galactan). The cell juice contains, in addition to sucrose, other soluble nonsucrose substances, or nonsugar substances, including invert sugar (0.1–0.2 %), raffinose (→ Carbohydrates, Chap. 2) (0.05–0.2 %), and kestoses (trisaccharides consisting of one molecule of D-fructose and one molecule of sucrose; i.e., fructosylsucroses); a soluble pectin–protein–hemicellulose complex; organic acids (oxalic, citric, tartaric, malic, etc.); proteins, polypeptides, glutamine, glutamic acid, asparagine, and other amino acids; betaine and other plant bases; nucleotides; saponins; enzymes; vitamins; the inorganic components potassium, sodium, calcium, and magnesium as cations; and phosphate, chloride, sulfate, and nitrate as the main inorganic anions.

Of the soluble nonsugar substances in sugar beet, 30–40 wt % is eliminated during purification of the juice (with Ca^{2+}-precipitable anions, pectins, proteins, Mg^{2+}); the remainder is left in the juice and prevents complete crystallization of the sugar, leaving a final syrup, molasses. In molasses, for 1 part of nonsugar substances, about 1.5 parts of sugar are present in the dissolved state. The loss of sugar in molasses is the largest single loss (i.e., 12–18 % of the sugar content of the beet).

For this reason, efforts are being made to predetermine the expected loss of sugar in molasses and/or the purity of the thick juice, which closely correlate with each other, from beet constituents that can easily be determined analytically (content of sugar, K^+, Na^+, α-amino-N, and invert sugar). The average values of these constituents, also called quality parameters, vary greatly from year to year, even in a limited area under cultivation (e.g., southern Germany). Thus, the content of potassium is 45–60 mmol/kg of beets, of

sodium 5–10 mmol/kg, and of α-amino-N 15–32 mmol/kg. Scientific papers of different authors concerning these quality parameters were summarized and compared in 1996 [60].

In controlled cultivation experiments, the ability to influence some quality characteristics was determined analytically [61]. The main influencing factors were found to be location and weather (Table 5). The statement that the influence of the variety is, at ca. 8 %, relatively low applies only when approved, time-tested varieties are compared with each other. The differentiation between varieties that are "good" and those that are "unsuitable" for a certain area under cultivation is considerably greater.

Apart from these chemical characteristics, the mechanical properties of the root, such as breaking and bending strength, elasticity, and cutting resistance, are of prime technological importance. Consequently, they are also significant for the economic success of beet sugar production.

6.3. Preparation

After harvesting, sugar beets are stable for only a limited time and should be processed as quickly as possible. For this reason, beet sugar factories operate for only part of the year (campaign), e.g., about 80–120 days (from the end of September to the end of January) in Central or Northern Europe and the United States. In more southern countries (e.g., Greece and Italy), work starts in July/August. About 2000–25 000 t of beets are processed per day, depending on the capacity of the factory. For economic reasons, most factories produce sugar for consumption immediately (white sugar factories). Only a few factories continue to produce raw sugar first, which is then processed into white sugar in refineries or other white sugar factories.

6.4. Delivery and Storage

For practical reasons, even larger fields must be harvested at one time. The harvested beets are either stored temporarily in clamps at the side of the field or transported directly to the factory. Before the transport vehicles are loaded, the beets are mechanically precleaned to reduce the dirt tare from $\approx$15 % at harvest to $<$ 10 %.

Mechanized harvesting has the disadvantage of delivering the beets along with leaf remnants, stones, and a lot of soil, especially in wet weather. This can lead to tremendous problems during processing (fluming, washing, cutting) in the factory. In the annual processing of 500 000 t of beets, an average of 60 000 t of soil accumulates (40 000 m^3).

If the separated soil cannot be reused – after being stored temporarily to restructure its mechanical properties – the profitability of sugar production is questionable because of the high costs of its disposal in industrialized countries.

Depending on long-term weather conditions, harvesting must be completed before the rainy season (e.g., in Italy) or frost (e.g., in Finland or Montana, United States) and long before the end of the working period. Therefore, a part of the harvest must be kept temporarily in field clamps or large piles on natural or paved ground.

To keep the loss of sugar during storage as low as possible, only ripe, healthy, low-damaged, and clean beets should be stored for longer periods. Sugar losses occur through respiration, since the sugar beet requires a certain amount of energy to maintain its vital functions, and through aerobic degradation or rot caused by yeasts, molds, and bacteria. Excessive mechanical damaging and bruising of beet causes higher sugar losses during storage, due to increased microbiological attack at the damaged surface and additional sucrose utilization of damaged beet to heal the injury. The optimal storage conditions for sugar beet are obtained when beets are piled in a uniformly porous manner: that is at no point in the pile should the hollow spaces between beets be able to get clogged with dirt, weeds, or broken pieces of beet. The porosity of the sugar beet pile should permit the heat generated by respiration, ca. 3000 kJ/t of beets per day, to be dissipated by natural ventilation easily and the temperature of the entire pile to be kept at + 2 to +4 °C. If necessary this low temperature can be maintained by forced air ventilation at night when the air is cooler. In addition, a porous sugar beet pile permits the relative humidity to be kept constant (ca. 85–95 %) so that the beets do not wither excessively (water loss) [62].

Until now, only unwashed sugar beets were believed suitable for storage. However, the opti-

Table 5. Influence of different factors on yield and composition of sugar beets, in percent

	Root yield	Sugar content	Potassium content	Sodium content	α-Amino-N content
Location	22.4	12.4	21.5	37.2	30.4
Weather	35.9	54.2	37.1	42.3	35.3
Time of sowing	25.5	3.3	4.4	3.7	1.2
N fertilization	0.8	3.0	0.7	2.4	20.9
Plant population	5.8	2.3	7.6	4.7	5.2
Time of harvesting	4.2	12.4	10.0	5.7	3.8
Variety	5.4	12.4	18.7	4.0	3.2

mal conditions for storage described above are achieved more easily if sugar beets are washed and then piled to a height up to 10 m. The moisture remaining on the beet surface can be removed by forced air ventilation, which in addition has the advantage of faster temperature reduction in the pile as a result of water evaporation [63].

Despite all preventive measures, sugar losses during storage cannot be avoided completely. Depending on the temperature in the sugar beet pile (+ 2 to + 10 °C), the losses are 150–200 g of sucrose per day per tonne of beets (0.015–0.020 % per day, beet based).

Frozen beets can be stored for long periods with only minor sugar losses [64]. However, they must be processed quickly after thawing because they rot easily. In the northern regions of the United States, to prevent thawing, beets are stored in free span insulated buildings where they freeze. The frozen beets are protected against sudden warm spells.

6.5. Thick-Juice Storage

The recommendations made until now for achieving a year round working period in sugar factories by preserving the beets (freezing, drying, etc.) have not gained acceptance because of their high costs.

Since the mid-1960s, the working period in some factories (e.g., in the United States, France, and Germany) has been extended by making the beet processing factory (parts of the plant preceding the sugarhouse), including the evaporating station, larger than the sugarhouse and by temporarily storing the thick juice in floating-roof tanks [65] with a capacity of up to 100 000 m^3. In tanks without floating roof, which are available at lower investment costs, the juice surface must be protected against yeasts by paraffin, formalin, or caustic soda solution [66]. With properly adjusted storage conditions in the bulk (DS content $\approx 67\,\%$, pH ≥ 9.0, temperature $< 15\,°C$, lowest possible microorganisms content), the thick juice can be stored for years without appreciable quality losses [67], but sometimes thick juice degradation was observed [68]. The profitability of this processing mode depends greatly on local conditions (costs for energy, labor and investment) [69].

6.6. Weighing and Sampling

After the first weighing (gross − tare = net mass), one representative sample is taken, usually mechanically and at random, from every delivery. This sample is used for the determination of dirt tare and partly for top tare [70], sugar content, and for the evaluation of quality. In the case of dry unloading with a wagon or truck tipper, beets are conveyed via a dirt separator (roller grate, wire rod screen) to stacks arranged on paved areas. In wet unloading according to the "Elfa" process, beets are washed out of the vehicle or wagon and pass through flumes to the washing stage.

6.7. Internal Transport, Washing

The beets are transported from the Elfa unloading areas or beet stacks to the actual washing stage in "flumes," concrete or tiled channels laid in the ground about 0.5–1.2 m wide with a slope of 1–2 %. The beets are transported by means of water and simultaneously freed from a large part of the beet tare. Flume channels made of steel sheet are also installed above ground. Trash separators in the channels intercept leaves, straw, and weeds (a type of mechanically operated rotating rake with free-swinging long prongs is suspended from the top of the channel), and a

rock catcher removes stones (the beet flow is led over an ascending water stream whose flow rate is such that the beets remain afloat and the stones sink). The beets are lifted from the flume channel to the level of the washing facility by wheels, screws, or inclined scrapers. Alternatively, the entire beet–water mixture is pumped up by mammoth pumps or one- channel centrifugal pumps (unfavorable because heavy damage is caused to the beets). Before the beets enter the washing facility, flume water is separated from the beet–water mixture with the help of square-roll screens or vibrating screens because part of the beet tare has already been separated from the beets and is contained in the flume water.

The dirt still adhering to the beets is subsequently removed in the washing facility. The beets are washed in trough washers, drums, washers with rotating agitating arms, or on vibrating screens. *Agitating washers* consist of long troughs that are divided into individual compartments and provided with cylindrical screens and a horizontal shaft. This shaft is equipped with stirring arms, transport arms, and throwers. At the bottom, the washers have stone catching compartments and hatches to allow periodic withdrawal of wastewater. The beets are rubbed together, and thus washed, by the movement of the stirring arms.

In *vibrating washers*, the beets are transported over a wedge-wire screen, which is made to vibrate by a circular or linear vibrator. At the same time, water at a pressure of up to 1 MPa is sprayed on the rotating beets from the top. Since the root canals of the beets are also touched by the water jet, the beets obtained when vibrating washers are used for the second wash are generally cleaner than those obtained after only one washing process.

The water requirement is as follows: for fluming, ca. 500–800 %, beet based; for washing, 150–200 %, beet based; and for the operation of a single stone catcher, 70–100 %, beet based. The sugar losses during fluming and washing are 0.05–0.5 %, beet based, depending on the extent of damage to the beets. Losses of < 0.2 % were given as standard for technological leadership [71].

6.8. Processing Wash and Flume Water

The flume and wash water contain beet particles. For this reason, all of the wastewater must first pass through separators. These are mechanical screening devices with round or slit perforations (0.6–4 mm) that remove beet and leaf fragments and root hairs from the water. The intercepted material is separated into its components in cyclone washers. Larger beet particles (> 2 cm) and tails are returned to the washed beets. Smaller particles are either led to the pulp dryer or used directly as feed.

The drained flume and wash water is led to wastewater treatment plants for mechanical purification (sedimentation). The thickened soil sludge, which contains most of the beet soil, is pumped into settling tanks equipped with drainage systems for dewatering and restructur-

ing soil. After two to three years, the soil is compact enough to be reused.

Attempts to remove the beet soil from the thickened sludge directly by means of sedimentation centrifuges did not give the expected results [72].

The mechanically clarified water is reused for fluming and washing (flume and wash water cycle). In this way, only 25–30 % (beet based) of industrial water (condensate) need be added to the water cycle as make-up during the last rinsing of the beets after washing. This quantity corresponds to the amount of water pumped off with the thickened soil sludge. To prevent excessive bacterial growth in the circulating flume and wash water, the addition of $Ca(OH)_2$ to the water to give a pH of 10–12 is appropriate. At the same time, the sedimentation of solid matter in the mechanical settling tank is improved.

Since the transport water pumped off with the soil sludge has a high organic contamination (COD 5000–10 000 mg/L), it is first subjected to anaerobic degradation with an efficiency of 90–95 %. The wastewater is subsequently subjected to aerobic treatment, and nitrification or denitrification, depending on the demands made on the composition of the wastewater to be discharged (e.g., total N content) [73].

Ammonium ions enter the wastewater through the vapor condensates of the evaporator station, which have a NH_4–N content of 100–200 mg/L, depending on the glutamine content of the beets. For this reason, ammonia can be eliminated from the condensates by air stripping [74].

Since the beets (water content $\approx$ 75 %) carry sufficient water into the production process, which accumulates as condensate, a factory today can largely do without ground or surface water. The total COD burden on the wastewater of a beet sugar factory is 2–3 kg per tonne of beets, with $<$ 1 kg attributed to leadership technology [71], and in the case of cane sugar factories, 14–25 kg per tonne of cane.

6.9. Slicing Beets

From the washing facility, the beets, beet fragments, and beet tails are transported by belts or bucket elevators to the slicer hopper, which is installed above the slicers. As far as possible, this bin should accept the amount of beets processed in an hour and should always be kept full (controlled via load cells) to guarantee uniform feeding of the slicers. The beets are weighed either before the slicer hopper (with a tipping weigher) or after slicing (with a conveyer scale). The weight of the "clean beets" obtained in this manner is used to calculate internal yield.

Besides, vertical shaft slicers with horizontal cutting disks, rotary drum slicers are being used increasingly for the slicing of beets. The output of slicers is controlled by altering their speed, and the set output required is controlled by the conveyer scale in the path of the cossettes to the extraction system. This scale sends out the impulse for output control. A constant supply of beet cossettes is required for good extraction, along with a constant mass flow in the following process steps.

A typical rotary drum slicer is shown in Figure 3 [75]. The beets enter the slicing drum via a feed hopper. As a result of the comma-shaped baffles, the rotating motion of the slicing drum (20–120 rpm), and the resulting pressure of the beet mass, the beets are cut by knives screwed into the knife boxes. Three knives, with a length of 200 mm each, are mounted side by side in a knife box,resulting in a cutting length of 600mm.

If a foreign body appears (stones, metal pieces, etc.), the stone catcher door springs open and the machine automatically comes to a standstill. Drum slicers are built with an output of up to 5000 t/d.

The zigzag Königsfelder knives are used most often today (Fig. 4). These knives should theoretically produce cossettes having a V-shaped cross section. Cossettes of 3–5-mm thickness result in surfaces of 2.5–3.5 m^2 per kilogram cossette, a cossette circumference of 25–30 mm, and a cross-sectional area of 15–35 mm^2.

Figure 4. Königsfelder knife

For evaluation of the quality of beet cossettes, two criteria have been introduced:

1) The Silin number gives the length in meters of 100 g of beet cossettes arranged in a row. Well- cut slices give a length of 10 to 16, depending on the spacing of the knives.
2) The "Swedish number" is the quotient "weight of cossettes $\geq$ 5 cm"/"weight of cossettes $\leq$ 1 cm" and has a value of 15–25 for good cossettes.

The mechanical strength (elasticity) of sugar beets has a great influence on cossette quality [76]. The preferred quality, which is slightly dependent on the type of extraction, are small, brittle cossettes.

7. Production of Juice (Extraction)

The extraction of beet cossettes is an important process step that greatly influences sugar losses and subsequent process steps. Upon extraction under sterile conditions with as little water as possible, extensive desugarization of the beet cossettes should be achieved and a raw juice of high purity and density (solids content) should be obtained.

7.1. Principles [77]

The sugar dissolved in cell juice can pass out of the beet cossettes (solid phase) into the extraction liquid only if the cell and vacuole membranes are either opened mechanically (e.g., by producing a finely ground pulp) or denatured thermally. When beets are cut, about 5–15 % of the cells are damaged mechanically to such an extent that an exchange can occur between the cell components, including those dissolved colloidally, and the extraction liquid. The remaining intact cells must be opened irreversibly by the action of heat. Denaturation of the cells should occur quickly (i.e., at the highest possible temperature) [78]. At 80 °C, 80 % of all the beet cells are opened in 5 min; at 70 °C, about 14 min is required to achieve the same result. The transfer of sucrose and other water-soluble nonsugar substances from the denatured cossettes to the extraction liquid occurs in two phases:

1) Transport from the inside of the cossettes to the surface
2) Transport from the surface of the cossettes to the extraction liquid through the entire distance of extraction

Since this is a disperse system, Fick's second law applies to the mass transport. However, mass transport is calculated more easily according to Fick's first law.

If ds is the amount of substance that diffuses in time dt through the surface F of the cossette at a concentration difference dc along the path dr, then

$$\dot{m} = \frac{\mathrm{d}s}{\mathrm{d}t} = D \cdot F \cdot \frac{\mathrm{d}c}{\mathrm{d}r}$$

The diffusion coefficient D for beet tissue is $\approx 1 \times 10^{-5}$ cm^2/min at 70 °C. According to the Einstein relation, the diffusion coefficient is temperature dependent. Consequently, the formulas give the dependence of practical juice extraction on temperature, cossette shape (surface), amount of extraction liquid (concentration gradient), and extraction time.

According to the formula, the extraction temperature should be as high as possible to accelerate mass transport. This can be fulfilled only within certain limits. Temperatures that are too high lead to impure, poorly processible raw juices because structural substances of the cell walls (pectin–araban–protein complex) are also degraded to a considerable extent and thus become water soluble. The following temperature course represents a compromise: the cossettes are heated to 70–78 °C for a short time (about 5 min) to denature the beet cells, and extraction is carried out at 69–73 °C. Optimal temperatures depend on the growth conditions of the beet (i.e., they vary from year to year) and on the equipment. They must be determined in practical operation.

The temperature in the extraction system also influences the vital functions of microorganisms. Soil bacteria, especially mesophilic bacteria, enter the extraction system with the soil still adhering to the washed beets (0.1–0.5 %). Possibly, other strains of bacteria enter the system via the extraction water. As a result of their metabolism, these bacteria cause sugar losses (a part of the "unaccounted losses") that, in the case of larger infections, can amount to 0.1–0.2 % of sugar (beet based). The turnover of mesophilic

bacteria can be limited by avoiding longer spells at the temperatures at which they grow best (< 40 °C) or even by killing them through exposure to higher temperatures. In contrast, thermophilic organisms (e.g., *Bacillus stearothermophilus, Clostridium thermohydrosulfuricum*, now named *Thermoanaerobacter thermohydrosulfuricus* [79]) are not inhibited by the temperatures allowed for extraction. For this reason, regular treatment of the extraction system with disinfectants (→ Biocides, Chap. 2.6, → Biocides, Chap. 2.8) (e.g., hydrogen peroxide, glutaraldehyde, peracetic acid, and especially 30 or 40 % formalin) cannot be avoided. A quantity of formalin equal to 0.5–1.0 % of the hourly raw juice volumetric flow rate (i.e., 50–100 kg per 100 m^3 of raw juice per hour) should be added suddenly. The interval between two additions depends on the intensity of the infection. In general, shock disinfection must be conducted every 8–24 h. Today, after the introduction of hops β-acids (BetaStab 10A), rosin acids, and myristic acid as antibacterials for beet extraction, it is possible to avoid addition of strong disinfectants, but at higher costs [80]. Enzymatic determination of the concentrations of L- and D-lactic acid has proved useful in monitoring the microbial state [81]. L-Lactic acid is the main acid formed microbially in the extraction system. Other carboxylic acids (acetic, propionic, and butyric acids), as well as ethanol, acetone, nitrite, hydrosulfide, and hydrogen can also be formed [79, 82]. Furthermore, pH measurements in the extraction system can be used to detect infection.

The demand for cossettes with a large surface area can be fulfilled to only a certain extent; otherwise, the permeability of the cossettes packet with regard to the juice is not guaranteed. This applies especially to equipment without forced charging. The charging of the extraction equipment, which is expressed as kilograms of fresh cossettes per hectoliter of extraction volume, should be as high as possible to achieve a high relative velocity between the cossette mass and the extraction liquid. In equipment without cossette-forced charging, a filling of 65–75 kg/hL can be achieved. A filling of up to 55 kg/hL is possible in extraction systems with forced charging of cossettes. Calculation of the velocity of the extraction liquid (the juice or operating velocity) is greatly simplified as follows:

$$w = \frac{S}{q_{\mathrm{f}}} = \frac{S}{q\left(1 - \frac{F_s}{d \cdot 100}\right)}$$

where w is the flow rate in meters per minute, S is the amount of raw juice in cubic meters per minute, q_{f} is the free cross section in square meters, q is the cross section of the extraction equipment in square meters, Fs is the cossette filling in kilograms per hectoliter, and d is the relative density of the cossettes [83]. Therefore, the velocity depends on the "raw juice draft" (i.e., the mass of raw juice that goes into the factory) and is expressed in weight percent (beet based). For thermal reasons, efforts are made to attain the lowest possible raw juice draft (i.e., weight of juice/weight of beet); it is normally 105–115 % (beet based).

Furthermore, the raw juice draft influences sugar losses during extraction. The losses are expressed as the sugar remaining in the desugarized cossettes, based on the beet mass processed. These "determinable extraction losses" are 0.12–0.28 % (beet based) in continuous plants with a juice draft of 105–115 % (beet based). This corresponds to an extraction efficiency for sugar of 0.97–0.99. Extraction loss is reduced by about 0.01 % (beet based) by increasing the draft by 1 % (beet based) in each case.

Parallel to a sucrose extraction of 97–99 %, approximately 20–30 % of the total nonsugars are extracted (i.e., about 70–75 % remain in the extracted cossettes). Thus, the purity of the raw juice is 89–91 %, compared to 68–72 % in the beets. Of the nonsugar substances in the beet, about 42 % of the total nitrogen, 88 % of the protein nitrogen, 72 % of the calcium ions, 34 % of the magnesium ions, and 17 % of the alkali ions remain in the pressed pulp. The alkaline-earth and alkali ions in the pressed pulp are, for the most part, present as pectates and pectinates [concentration ca. 70 milliequivalents (meq) per 100 g solids of pressed pulp]. Thus, the degree of extraction for cations is influenced decisively by that of the pectic substances. About 95 % of the pectins introduced with the beets normally remain in the desugarized cossettes. About 95 % of the low molecular mass water-soluble anions in beet are extracted. Since part of the extracted nonsugar substances is precipitated during the juice purification step, a higher sugar yield is also achieved with better desugarization [84].

The extraction time should be short to avoid the prolonged action of heat, which increases the solubility of the structural substances of the cossettes. However, extraction times for the solid phase of 70–75 min, and up to 130 min with some equipment, are required to attain good extraction efficiency. The extraction water used to produce the juice should be free of thermophilic bacteria and preheated to 65–72 °C. The pure condensate obtained on evaporation of the thin juice is well suited to this purpose. The extraction water is adjusted to pH 5.6–5.8 with sulfur dioxide, hydrochloric acid, or sulfuric acid.

The ability of the structural substances to be pressed mechanically is improved by converting the carboxyl groups of the pectins as much as possible to calcium carboxylates. For this reason, 350–700 mg/L of calcium ions in the form of calcium chloride or calcium sulfate are usually added to the fresh extraction water [85]. In this manner, pressed pulp with a solids content of 28–35 % can be produced by purely mechanical means. Since about 90 % of the salts and acids in the extraction water pass into the raw juice and are only partially precipitated during juice purification, a high salt content in the extraction water lowers the purity of the thin juice.

The beet-based quantity of extraction water is calculated as follows:

$$\begin{aligned}&\text{Quantity of extraction water in \% (beet based)}\\&\quad = \text{raw juice draft in \% (beet based)}\\&\quad + \text{pressed pulp obtained in \% (beet based)} - 100\end{aligned}$$

Water quantities of 25–30 % (beet based) are used. Apart from the fresh extraction water, the "press water" serves as an extraction liquid. This water is obtained on pressing the desugarized "wet pulp" from 7–9 % solids content to 18–35 % solids content (pressed pulp). Since the press water contains 0.6–2.5 % sugar, it must be returned to the extraction system "below" the point of addition of extraction water. Depending on the initial and final solids content of the pressed pulp, 35–65 % (beet based) press water is obtained. The press water cycle, including the entire pulp pressing station, is very susceptible to infection. For this reason, efforts are made to have short residence times (small pump recipients, short piping, no collection boxes, etc.) and to reheat the press water to 68–71 °C as quickly as possible. The advantages of recycling the press water compared to using only fresh water are no accumulation of wastewater during extraction, a lower extraction water requirement, an increase in the pressed-pulp solids obtained by 0.3–0.4 % (beet based), higher-quality pressed pulp that contains about three times the sugar of pressed pulp obtained by using only fresh water (sugar content of 6 % compared with 2 % of the solids), and lower extraction losses.

The mathematical control of juice production includes daily determination of the extraction losses, the amount of pressed pulp obtained, and the raw juice draft in percent (beet based). In addition, the sugar content (polarization, Pol) and the dry substance (DS) of the fresh cossettes (FC), pressed pulp (P), and raw juice (RJ) must be determined analytically. Although rare, the amount of pressed pulp obtained can also be determined by weighing. According to the calculation proposed by F. Schneider [86], the amount of sugar X_1 obtained in the raw juice is determined first:

$$X_1 = \frac{\mathrm{Pol_{FC}} \cdot \mathrm{DS_p} - \mathrm{Pol_p} \cdot \mathrm{DS_{FC}}}{\mathrm{DS_p} - \frac{\mathrm{Pol_p} \cdot \mathrm{DS_{RJ}}}{\mathrm{Pol_{RJ}}}}$$

(in % Pol, beet based)

The extraction loss is then

$$X_2 = \mathrm{Pol_{FC}} - X_1$$

the raw juice draft is

$$\frac{X_1}{\mathrm{Pol_{RJ}}} \cdot 100$$

the pressed pulp obtained is

$$\frac{X_2}{\mathrm{Pol_P}} \cdot 100$$

all three in weight percent, beet based. These formulas are valid only in a closed system (i.e., when no wastewater is produced).

7.2. Extraction Technology

The *batchwise operating diffusion battery* (→ Liquid–Solid Extraction) has now been largely replaced by continuous extraction systems (see below). Diffusion batteries consist of 8–16 cylindrical vessels that have a conical top and bottom, and a net capacity up to 12 m^3. Except for two diffusers that are, in each case, being emptied or filled with fresh beet cossettes, all the others are connected in series to a battery.

The juice flows from the top to the bottom countercurrently to the slices.

The *continuous extraction process* was introduced to reduce extraction losses, to avoid wastewater (effluent water), and for purposes of rationalization. Continuous extraction systems can be divided into equipment *without cossette-forced charging,* equipment *with cossette-forced charging*, and equipment *with cossette- and juice-forced charging* [87].

In equipment *without the forced charging of cossettes,* the extraction liquid flows steadily countercurrent to the cossette mass. The cossettes are transported within the extraction area with relatively simple internals (e.g., screws). Examples of this type of equipment are the BMA tower, the Buckau-Wolf tower, and the DdS diffuser. The BMA tower and the DdS slope diffuser are described here (Sections 7.4.1 and 7.4.2).

In equipment *with forced charging of cossettes*, the cossettes are drawn through the extraction area with a special transport system, which consists of endless chains with conveying elements. The Olier system belongs to this type of equipment and is similar in design to a chain conveyor extractor (→ Liquid–Solid Extraction).

Systems with *forced charging of cossettes and juice* consist of a number of cells in which the material being extracted and the extraction liquid move cocurrently for a time. However, countercurrent extraction is obtained on the whole because the extraction liquid or the feed is, in each case, returned to the preceding cell [88]. Examples of this type of system are the RT continuous drum [89, 90] and the De Smet diffusion system (see Section 7.4.3), which is also called trickle diffusion.

The best technological results have been obtained with further development of the RT continuous diffuser. However, this system requires the highest specific investment costs and has the greatest space requirement. Throughout the world, extraction towers, DdS slope, and RT systems are most frequently installed in beet sugar factories.

For a survey of the historical development of equipment and machines for the extraction of juice, evaporation, crystallization, and separation, see [90].

7.3. Extraction with Nonaqueous Solvents

Extraction with nonaqueous solvents has not achieved commercial importance although appropriate experiments with methanol, ethanol, mixtures of these with polyhydric alcohols [92], and liquid ammonia [93] as extracting agent have been conducted repeatedly on a pilot scale. Since these processes can only use dried beet cossettes, they are not profitable because of the high costs of drying and storing cossettes, despite the possibility of year-round operation.

7.4. Extraction Systems

Extraction plants are complex. They consist of:

1) The actual extraction equipment
2) The system for denaturation of the beet cells, which is used simultaneously as a heat exchanger to obtain raw juice that is as cold as possible
3) The pulp pressing station, the resulting press water being returned to the extraction step

7.4.1. BMA Extraction System [90]

The BMA extraction system, supplied by Braunschweigische Maschinenbauanstalt AG, Braunschweig, is depicted in Figure 5.

"Fresh cossettes" from the slicer (a) are denatured in a horizontal countercurrent mixer (c) with the "tower juice", which is warmed up in the preheater (f). The cossette–juice mixture is deaerated and brought to extraction temperature before being pumped (h) into the bottom of the extraction tower (j). The tower juice cools down in contact with the cold cossettes, washes the cell juice out of the opened beet cells by convection, and is withdrawn from the system as raw juice at 20–30 °C through a front screen and via pump (g).

In the extraction tower, the cossette mass is led from the bottom to the top countercurrently to the extraction liquid with the help of suitable internals (e.g., a rotatable tube inside the tower with stirring arms that interact with baffle plates connected to the outer wall). The extraction freshwater fed at the top and press water fed

a little lower down are preheated (65–70 °C) so that the extraction tower need not be heated.

The desugarized cossettes are discharged at the top and led via screws to the pulp pressing station, where they are pressed to give *pressed pulp* with a solids content of 18–22 %, if used directly, or 22–35 % if dried.

The press water is freed of smaller beet marc particles by rotating or vibrating screen surfaces or sieve-bend screens. It is then heated in preheaters and returned to the extraction system. The pH of the press water should be 5.0–5.5. If the pH is higher, it is adjusted by addition of acid, as in the case of freshwater extraction. If the pH is lower, the press water cycle contains bacteria and must be disinfected. But after a rapid increase of energy costs in 1973, some sugar factories started to operate towers with intentional growth of microorganisms and concomitantly lower pH of press water to improve pulp pressing [91].

Extraction plants of this type were built with a maximum beet processing capacity of 12 000 t/d, but are often operated at higher than nominal rates. The extraction tower has a diameter of 11.0 m and a height of 21.6 m; the countercurrent mixer has a diameter of 6.7 m and a length of 8.5 m. The tower and circulation juice are about 1000 % (beet based) in circulation. For this reason, the circulation juice has to be heated by only ca. 2–3 K to introduce the required amount of heat. The time of extraction is 70–85 min, including 8–10 min in the scalder. At a raw juice draft of 106–115 % (beet based), extraction losses of 0.19–0.25 % (beet based) are obtained.

7.4.2. Extraction with the DdS Slope Diffuser [90, 94]

In contrast to extraction towers, the DdS slope diffuser (Fig. 6) of the De danske Sukkerfabrikker, Copenhagen, consists of a single piece of equipment, a trough (apart from the cossette pressing station). This trough is inclined at about 8°; it is ca. 25 m long, and 4–7 m wide. The cossettes are transported from the bottom to the top against the flow of extraction liquid by two parallel interworking transport screws. The trough is heated by 12 steam caps attached to its outer jacket. Because of the good heat exchange throughout the trough, this system made it possible for the first time to obtain raw juice with a temperature of 20–25 °C. At a raw juice draft of 109 to 116 % (beet based), extraction losses of 0.14–0.26 % (beet based) are obtained [95]. A disadvantage of the DdS slope diffuser is the long residence time of the cossettes in the apparatus (about 125–140 min). These plants are

built up to a beet processing capacity of 5000 t/d.

7.4.3. Extraction with the De Smet System

The De Smet system(→ Liquid–Solid Extraction) belongs to the type with forced charging of cossettes and juice. A compact cossette layer with a height of 60–70 cm is moved intermittently forward at a speed of 3.2 cm/min on the upper part of an endless, horizontal wedge-wire screen (ca. 5 m wide, total length 75 m) moving on two guide rolls. The extraction liquid trickles constantly through the entire cossette layer from the top downward in 18 partial streams. The liquid is collected under the screen in compartments and pumped into the juice gutter above the next compartment against the cossette flow. From here, the juice again trickles through the cossette layer. In this manner, countercurrent extraction is achieved on the whole, although cocurrent extraction occurs in individual steps. With a raw juice draft of 108–115 %, sugar losses of 0.14–0.30 % (beet based) are obtained [87].

7.4.4. The RT-5 Continuous Extractor

The RT-5 extractor [88 – 90] consists of a rotating cylindrical drum having a double screw system, similar to an Archimedes screw, welded to its inner wall. Thus, the residence time of the extraction liquid is very short (≈ 30 min), and the residence-time distribution is very narrow. The cossette mass is present in weighed partial amounts in each of the "compartments." With each rotation, it is lifted out of the extraction liquid and transported forward by two compartments with the help of grates (screens) (number of compartments ≈ 35). To ensure smooth operation of the drum, the lifting of cossette packets is carried out in accordance with the number of compartments, staggered in time, over a period of one rotation of the drum. This elaborate design gives excellent technological values and low extraction losses at a low raw juice draft. The maximum capacity of the RT-5 extractor is 13 000 t of beets per day, the length being 63 m, the diameter of the denaturation compartment 8.95 m, and that of the heat exchange compartment 7.5 m.

7.5. Pressing Extracted Pulp [82, 96]

Two types of presses exist: The single-screw vertical press and the swing screw horizontal pulp press. The presses consist of a cylindrical jacket with a screen pack in which a conical press screw (spindle) rotates (1–4 rpm). The spindle is equipped with spirals and a sieve covering. The ring opening at the end of the press spindle can be made wider or narrower by means of a "cone." Thus, constant pressure can be maintained with a changing output. Pressing is achieved by the fact that the passage volume is diminished progressively due to the conical form of the spindle body and the reduction of pitch of the screw. Press water is withdrawn from the screen jacket and press spindle by means of tubing. A *single-screw vertical pulp press* with a spindle diameter of 4 m and a height of 19.6 m can press cossettes from 3000 t of beets per day. Since the mid-1960s, a *swing screw horizontal press* (produced by Stord–Bartz Industri, Bergen, Norway), operated according to the double screw principle. Today (early 2000s) presses by BMA

(single screw), Babbini (double screw) and Stord (double screw) are installed with maximum capacities of 3500–5000 t/d, based on sliced beet and 30 % dry substance in pressed pulp [1]. Vertical double screw presses supplied by Babbini are among the latest developments [97].

Pressed pulp with a solids content up to 35 % can be obtained by optimization of the operating parameters and further development of construction details. Efforts are being made to attain a solids content that is still higher by double pressing or diffusive dewatering (up to 50 %). For the drying of beet cossettes, see Section 22.5. For uses, see also Section 22.5.

8. Juice Purification

The raw juice with a solids content of 13–17 % has a grayish black, opalescent appearance. Its color is caused by melanin, a blackish pigment, which is formed in the presence of air by tyrosinase (E.C. 1.10.3.1) from the tyrosine in the cell juice via dihydroxyphenylalanine (DOPA) and quinoid compounds. In addition, polyphenol–iron complexes contribute to the color of the raw juice [98].

The raw juice contains almost all the colloidally dispersed and molecularly dissolved substances (see Section 7.1) present in the cell juice of the sugar beet. It also contains the acids and salts present in or added to the extraction water, the metabolic products (L-lactic acid, acetic acid) formed microbiologically during extraction, methanol and acetic acid formed by the demethoxylation and deacetylation of pectin, and suspended particles consisting mainly of pectin–hemicellulose–proteins, macroscopic fibers, and cell residue as well as sand. The composition of the colloid fraction is largely influenced by the temperature course used in juice production (see Section 7). Raw juices have approximately the analytical values given in Table 6.

Until now, attempts to crystallize sugar directly from the raw juice without juice purification have not achieved importance [99].

The main purpose of juice purification is largely to remove the nonsugar substances contained in the raw juice and thus to increase the ratio of sucrose to total solids content (i.e., the purity of the juice) as much as possible. In this process, only those processing aids and reaction conditions should be used that, as far as possible, avoid not only the destruction of sucrose but also the conversion of nonsugar substances to compounds (e.g., colorants) that impede further processing of the juice.

Before juice purification, the fibers and cell particles suspended in the raw juice should be removed if possible. These particles would otherwise give rise to degradation products that have a negative effect on juice quality [100]. Sand should also be eliminated from the raw juice (e.g., by means of hydrocyclones).

The juices are heated to 60 °C before purification. In juice production, efforts are made to obtain a raw juice that is as cold as possible. For the first heating residual heat can be used (pan vapors of ca. 75 °C, condensates), which cannot be utilized otherwise and would save 2–4 kg of steam per 100 kg of beets. However, working with cold raw juice can result in bacterial infections and, consequently, sugar losses and filtration problems.

The heating devices used primarily are standing tubular heat exchangers and, increasingly, spiral-plate and plate-type heat exchangers. The juice in the heat exchangers should flow with a rate of less than 2 m/s so that the sludge particles agglomerated in the precipitation reactions are not destroyed again.

8.1. Lime–Carbon Dioxide Treatment

Colloidally dispersed or molecularly dissolved nonsugar substances can be precipitated out of the raw juice with additives. Of the many substances that have been tested (see, e.g., [101]), only quicklime, which was introduced more than 100 years ago, is of industrial importance. It is available everywhere, and its activity, cheapness, and easy applicability cannot be surpassed by any other substance. Furthermore, the carbon dioxide (CO_2) used today solely to remove excess lime from the juices (carbonation) is obtained as a side product (lime kiln gas) in the production of quicklime from limestone. For this reason, juice purification generally refers to lime–carbon dioxide treatment. Even ion-exchange processes have not been able to displace lime–carbon dioxide juice purification, although only 30–40 % of the nonsugar substances

Table 6. Analytical values of raw juice

Quantity	Analytical values of raw juice	Quantity	Based on 100 g DS
Solids content, %	15–18	Ash content, %	2.50
Sugar content, %	13.2–16.4	Invert sugar content, %	0.40–0.60
Purity (see Section 5)	89–91	Total nitrogen content, %	0.48
Acidity (as % CaO) against phenolphthalein	0.022	Pectin plus proteins content, %	≈0.61
pH	≈ 6.2	Cation content	35–45 meq
		Anion content	40–50 meq
		Amino acid content	10–20 meq

are removed by the latter process, whereas ion exchange eliminates up to 85 %.

An optimal juice purification with lime–carbon dioxide should simultaneously fulfill the following requirements as far as possible [102]:

1) Precipitation or flocculation of the pectin–hemicellulose–protein complex and other high molecular mass nonsugar substances (araban, galactan, etc.).
2) Precipitation of anions, such as phosphate, sulfate, citrate, malate, oxalate, polygalacturonates, that give poorly soluble calcium compounds with calcium ions, and precipitation of magnesium ions as magnesium hydroxide. The higher the content of anions precipitable with CaO in proportion to the total anion concentration, the greater is the excess of alkali ions (potassium, sodium) present in the second carbonation (see page 26) in the form of carbonate and hydrogencarbonate salts. This is connected with a low residual lime content in the thin juice. About 30 % of the total cations and 40 % of the nitrogen-free anions of the raw juice are precipitated during juice purification.
3) Alkaline degradation of invert sugar, galactose, and, partially, galacturonic acid present in the raw juice. In this process, ca. 1.9 meq of acid – 50 % of which is lactic acid (racemic mixture of D- and L-lactic acid) – is obtained from 1 mmol of saccharide. Furthermore, formic, acetic, arabonic, and saccharinic acids are formed. Lighter thin and thick juices are obtained by degradation of invert sugar in the presence of atmospheric oxygen. In this way the formation of degradation products bearing carbonyl groups is prevented, which can immediately react with the amino acids in the juice to give precursors of Maillard products [103].
4) Hydrolysis of glutamine to pyrrolidonecarboxylic acid and, in part, of asparagine to aspartic acid. All known juice purification methods fulfill this requirement incompletely because the temperatures, residence times, and pH values used during juice purification are not sufficient for glutamine hydrolysis. Almost complete glutamine hydrolysis occurs only during the first two steps in the evaporator station, with all the accompanying disadvantages. These include lowering of the pH of the thick juice and re-formation of invert sugar, with subsequent colorant formation and corrosion in the evaporator station. The ammonia generated in glutamine hydrolysis passes over with the vapor condensates (ammonia content 100–200 mg/L). The other amino acids present in raw juice are influenced only slightly during juice purification. Ornithine and lysine are preferentially incorporated into Maillard products. Small amounts of glycine and γ-aminobutyric acid are formed from threonine and serine or glutamine via pyrrolidonecarboxylic acid and its decarboxylation product [104]. γ-Aminobutyric acid further reacts with galacturonic acid or its oligomers to give tagaturon-γ-aminobutyric acid or its derivatives. These are intermediates in the Maillard reaction that gives rise to very highly colored compounds [102].
5) Other nonsugar substances that are not precipitated in the first carbonation, primarily colorants and multivalent anions (citrate, oxalate, etc.), should, if possible, be adsorbed on sludge particles or on the surface of freshly formed calcium carbonate crystals (second carbonation).
6) Prevention of chemical [102] and bacterial degradation of sucrose.

Apart from these chemical requirements, optimal juice purification must also produce an easily settleable and filterable sludge. Almost all the chemical analytical values (e.g., color, residual lime content) deteriorate when filtration problems occur, and turbid juice is obtained (with a turbidity level > 10 mg/L). In classical juice purification, safe filtration can be achieved only when part of the precipitate formed in the first carbonation is returned to the preliming stage.

The requirements for optimal juice purification presented above are influenced by process engineering parameters, such as the following:

1) The total mass of calcium hydroxide added and distributed to the individual process steps determines the activity of calcium ions and the pH of the juice in the individual juice purification steps.
   The CaO required for juice purification is 70–90 %, based on the mass of the nonsugar substances introduced with the raw juice. This corresponds to about 0.8–1.3 kg of CaO per 100 kg of beets. Of the total CaO mass, 10–12 % is added for preliming, 5–7 % to the thin juice 1 (see page 26) before the second carbonation, and the rest for main liming.
   Only the $Ca(OH)_2$ content dissolved in the juice is chemically active. Since calcium hydroxide is more soluble in cold sugar solutions than in warm solutions (35 g of CaO per liter of thin juice at 30 °C compared with 5 g of CaO per liter at 80 °C), the addition of milk of lime and the "chemical reaction steps" should be carried out at the lowest possible temperature. The rate of dissolution of calcium hydroxide in juice depends on the composition of the quicklime (magnesium, aluminate, and silicate content), the burning conditions (hard or soft burning), and the lime slaking technique used, especially the temperatures arising in the pores of the quicklime.
2) The volume of carbonation slurry or slurry concentrate returned to the preliming step. In general, the amount of precipitate returned to the preliming stage with the first carbonation slurry or slurry concentrate is such that the total CaO content in the preliming step is 8–12 g/L.
   Apart from this recycling of carbonation sludge to improve the filtration properties of the juices, the juice must be circulated, especially within the first carbonation, to achieve complete dissolving of calcium hydroxide particles. In general, circulation of six to seven times the quantity of juice via a detention vessel is sufficient. This measure also prevents calcium hydroxide particles from being sheathed by calcium carbonate crystals in the first carbonation and prevents secondary reactions during further processing of the first carbonation slurry (incrustation of the filter cloths, etc.). Furthermore this measure improves the exchange of materials during carbonation.
3) The temperature course during the individual steps of juice purification. Generally, the colors of thin and thick juices are better when the first steps of classical juice purification (preliming and main liming) are carried out at lower temperature (30–40 °C). Today, for fuel economy reasons, a temperature of 55–60 °C is generally used for preliming. Main liming is conducted at 85 °C. A temperature of 85 °C is also used for the first carbonation. If the heat loss in the first carbonation is very high, the first carbonation slurry should be heated to 85–90 °C to obtain better filtration properties. The second carbonation should be conducted at ≥ 94 °C.
4) The residence time during the individual process steps (i.e., the average residence time and the residence-time distribution in the case of continuous operation). The usual average residence time for the individual process steps is

Preliming	20 min
Cold main liming	5 min
Hot main liming	20 min
First carbonation	15 min
Addition of lime before second carbonation	5 min
Second carbonation	
Bubble column	12 min
Reaction vessel	10 min
	87 min

5) The composition of the carbonation gas (carbon dioxide and oxygen content) and the type of gas distribution in carbonation. These substantially influence the exchange of materials (gaseous–liquid and liquid–solid) and the exploitation of carbonation gas.
   In the carbonations, for precipitation of the calcium hydroxide mass mentioned above, 3.41 kg of lime kiln gas per 100 kg of beets is

required in the first carbonation, and 0.72 kg per 100 kg in the second, if the lime kiln gas has a CO_2 content of 40 vol %. For the product of the liquid side mass-transfer coefficient (k_L) times the specific interface (a) for carbonations used today, the following $k_L \times a$ values are calculated: $\approx 250\ h^{-1}$ for the first carbonation and $\approx 50\ h^{-1}$ for the second carbonation at superficial velocities of v_0 = 30–40 cm/s for the first carbonation and v_0 = 8–10 cm/s for the second.

Compared to bubble columns used in other industries, the $k_L \times a$ values for the carbonations are too low, and the superficial velocities too high. This means that the design of the actual carbonation vessels (bubble columns) is not yet optimal.

The values also imply that the installation of mechanical stirrers cannot produce an improvement in the operation of carbonation vessels, especially for the second carbonation.

The average crystal diameter and the crystal-size distribution of the calcium carbonate precipitates formed in the carbonations depend on the temperature and the calcium ion concentration in the juice. The higher the temperature, the coarser are the crystals, and the higher the calcium ion concentration, the finer is the average crystal diameter. Presently, the average crystal diameter obtained (mass distribution) is between 7 and 10 μm.

6) The manner in which carbonation sludge is separated from the juice, i.e., whether direct filtration is employed, e.g., via chamber filter presses (→ Filtration), with decanters and drum filters (→ Filtration, Chap. 8.6), with thickening filters and drum filters, with press filter automatic machines (→ Filtration), or membrane filter presses. During the contact time of the precipitated nonsugar substances with the juice, partial redissolving of the precipitate and other undesirable chemical reactions occur, including acid formation by alkaline degradation of nonsugar substances and sugar. For this reason, the separation of precipitate and juice should occur quickly.
7) The design of the equipment for individual process steps [102]. This applies not only to the reaction vessels, but also to pumping vessels, intermediate containers for juice, etc. These vessels should be designed in accordance with the principle "first in, first out."
8) The maintenance of optimal pH values during preliming, and first and second carbonation, which substantially influences the success of juice purification.

The industrial purification process consists of individual operations. Apart from the main processes described below, numerous process variations are known.

Classical Juice Purification. Classical juice purification consists of preliming, main liming, first carbonation, first sludge separation, second liming, second carbonation, second sludge separation, possibly sulfitation, and safety filtration. The process is represented schematically in Figure 7.

Preliming. In the preliming operation, raw juice is subjected to stepwise alkalinization with milk of lime (ca. 200 g of CaO per liter) up to a concentration of 0.12–0.25 wt % CaO, based on the juice. Today, progressive preliming is used almost exclusively (i.e., the pH of the raw juice is raised slowly from 6.2 to 10.8–11.4). The optimal pH to be maintained can be determined in the laboratory [105]. The optimal pH for the first carbonation is determined in a similar manner.

For preliming, horizontal U-shaped troughs [106] or vertical cylindrical vessels [102, 107], with forced charging of the juice, are used. In both cases, milk of lime is added at the end of preliming, and the pH steps in the individual compartments are achieved by back-mixing of a part of the juice in each case. The slow stepwise increase in pH from 6.2 to 11.4 has proved advantageous for effective precipitation and for stabilization of the precipitated substances because the colloids present in the raw juice have no uniform coagulation optimum.

The carbonation sludge to be recirculated should be added to the juice at pH 8–9 so that the colloids that start to precipitate are already provided with adsorption surfaces such as $CaCO_3$ crystals. In addition, the sludge particles returned are "overcarbonated" due to the lower pH, becoming dehydrated and less soluble. The more carbonation slurry concentrate or slurry is circulated, the better are the sedimentation and filtration properties of the juice. Less than the newly produced carbonation sludge should be circulated (i.e., no more than 1 volume of slurry per volume of raw juice in the case of carbonation slurry or 0.15–0.25 volumes per volume of raw

juice in the case of slurry concentrate). The recycling causes simultaneous juice dilution, which has a favorable effect on colloid flocculation.

Most of the nonsugar substances are precipitated in the prelimer; i.e., the purity of juices ranging from normal to thin juice 3 (see Section 8.1) differs only slightly from that of the clear preliming juice. However, the preliming floc formed can be separated from the juice only with difficulty.

Only in the *Sepa process* [108] is the carbonation sludge separated after the preliming operation. In this process, the preliming precipitate is dried together with molasses on pressed pulp (see Section 22.5) and then used as feed. The preliming juice is heated to 90 °C and subjected to defeco- carbonation (see Section 8.2.1) to load the flocculated colloids. However, the CaO added should not cause the total CaO concentration in the juice to exceed 0.5–0.6 %. The carbonation slurry obtained in this way is thickened with the help of decanters, and the resulting slurry concentrate is again concentrated in self- cleaning disk centrifuges. The thick sludge with ca. 78 % settleable substances is filtered through drum filters, and the desweetened filter cake is very finely dispersed in ca. 1.8 % of molasses (beet based). The homogenized mixture is sprayed onto pressed pulp. The clear juice from the decanter and filter is again subjected to defeco- carbonation, the juice being further processed as in normal juice purification processes. This method gives strongly colored thick juices.

Main Liming. In the main liming operation, CaO is added to the juice up to an alkalinity of 0.8–1.3 wt % CaO, which results in a total CaO concentration in the main liming juice of 1.8–2.5 wt %. Apart from the chemical reactions at high alkalinity, especially the destruction of invert sugar and amide hydrolysis, calcium hydroxide causes the formation of so much calcium carbonate in the first carbonation that the slimy flocculate formed during preliming becomes enmeshed and filterable. Since 2002, lime addition is often controlled by the filterability of juice, according to the LIMOS method [109], in order to lower the gross consumption of limestone ($CaCO_3$) to values < 2.5 % (beet based).

For the main liming operation, the vertical or horizontal vessels used are connected in a cascade and provided with slow stirrers [104]. The duration of main liming depends on the temperature: the residence time of the juice should be about 25 min at 80–85 °C or 15 min at higher temperature (up to 92 °C).

As a result of the better dosing ability, CaO is now added almost exclusively in the form of milk of lime (wet liming). The dry liming pro-

cedure used earlier, in which the quicklime was slaked directly in the juice, is seldom employed [110] because local overheating could cause sucrose destruction and discoloration of the juice.

First Carbonation [111]. In the first carbonation, excess calcium hydroxide in the juice is partially converted to calcium carbonate with carbon dioxide (carbonation gas). Thus, a filter aid for enmeshing the precipitated colloids (see above) and a surface for the adsorption of nonprecipitable nonsugar substances are produced. Furthermore, part of the ammonia – formed in the main liming by hydrolysis of the amides – and other gaseous organic substances are eliminated from the juice by the passage of carbonation gas. The resulting saturation of the exit gas with water vapor is connected with a heat loss of ca. 6000 kJ per 100 kg of beets. This can, however, be avoided by means of a suitable switch in the process flow [112]. The end point of the first carbonation is reached at pH 10.8–11.4, which corresponds to an alkalinity of 0.07–0.12 % of CaO in the filtered juice (*thin juice 1*). At lower pH (overcarbonation), part of the precipitated colloids is redissolved and the quality of the juice deteriorates. The temperature of the first carbonation should be 85 °C.

To exploit the carbonation gas sufficiently (≈ 85 %), it is passed countercurrently at a juice level of 5–6 m through the juice that enters from the top.

First Sludge Separation. After the first carbonation, the first carbonation slurry, which is heated to 90–95 °C and has a sludge content of 50–60 g of solids per liter, depending on sludge recycling, is separated in decanters into clear juice and slurry concentrate. The decanter volumes required are about 100–120 % of the slurry volume. Suitable decanters are thickeners with rakes or thickeners without forced discharging of the slurry concentrate. The concentration of sludge in the slurry concentrate is 2.5–5 times that in the carbonation slurry.

Sludge separation can be simplified by the use of "thickening filters," which immediately give a filtrate free from turbidity and a greatly thickened slurry concentrate. In *thickening filtration*, the carbonation slurry is filtered directly through continuously and batchwise operating filters. Thus, the residence time of the juice in the decanter is eliminated, and no heat is lost due to cooling. The level of turbidity in the filtrate obtained is generally so low that postfiltration is unnecessary. The sludge content of the slurry concentrate from filter thickeners is five to seven times that of carbonation juice. Cloth-covered tube filters are used preferentially for thickening filtration [113].

Of the total slurry concentrate obtained, ca. 45 vol % is returned to the preliming stage, and about 55 vol % is filtered through multicompartment or single- compartment drum filters (vacuum or pressure drum filters). In this process, 20–30 m^2 of filter surface is required for 1000 t of beet processing per day, depending on the sludge content of the slurry concentrate. The capacity of vacuum drum filters is 0.5 m^3 of clear juice per square meter per hour.

The carbonation sludge is washed on drum filters with about 80–100 % of hot water (condensate), based on the sludge volume, until a sugar content of 0.1–1.0 % is attained (desweetened). Depending on the lime added in juice purification, 8–10 % (beet based) of sludge is obtained with a solids content of 45–50 %.

The decantated material (level of turbidity 50–100 mg/L) and the drum filter filtrate (level of turbidity 200–500 mg/L) are refiltered separately or together through ceramic or cloth- covered tube filters (→ Filtration) or bag filters (→ Filtration). The level of turbidity in the postfiltered juices is less than 10 mg/L. In the case of cloth- covered filters, the capacity is ca. 2–3 m^3 m^{-2} h^{-1}. If thickening filters are used, the drum filter filtrate is returned to the first carbonation.

To immediately obtain a spreadable carbonation lime cake that can be used as fertilizer lime, automatic membrane filter presses (→ Filtration) or automatic press filters (→ Filtration) [114] are being used increasingly for filtration of the slurry concentrate. These automatic machines produce "carbolime" with a solids content of > 70 % and a CaO content of > 30 %, which is a suitable fertilizer lime. The composition is given in Table 12.

Second Carbonation. In the second carbonation step, more carbon dioxide is led into the filtered juice from the first carbonation to convert the remaining calcium hydroxide to carbonate and, in addition, to transform the alkali present in the juice, mainly potassium hydroxide, into hydrogencarbonates or carbonates. In a secondary reaction, the calcium bound to organic acids or complexes is partially precipitated as carbonate.

A sufficiently low residual lime content cannot always be attained in the thin juice 2 (<30 mg CaO/100 g DS). Further softening can be achieved by adding aqueous sodium hydroxide–sodium carbonate to thin juice 1 or by ion-exchange treatment of thin juice2 (see Section 14.1).

To increase the adsorption of nonsugar substances by increasing the calcium carbonate crystal surface and to improve the filtration properties of the second carbonation juice, 0.1–0.2 % CaO, juice based (after filtration of the first carbonation juice), is added to thin juice 1 before the second carbonation. The temperature of the second carbonation should be 94–98 °C. A pH between 8.9 and 9.2 (alkalinity 0.015–0.022 % CaO) is maintained as the end point of the second carbonation, at which the remaining residual lime content in the filtered juice (*thin juice 2*) is at a minimum.

The juice reaching the second carbonation must not contain any sludge particles (i.e., it must be free of turbidity after filtration) because these particles would otherwise redissolve. Even very little residual sludge produces the juice shade characteristic of overcarbonation and a noticeable deterioration in color [115].

As in the first carbonation, cylindrical vessels with a juice level of 5–6 m are also used in the second carbonation. In contrast to the first carbonation, the second is often carried out cocurrently, juice and carbonation gas being introduced into the vessel from the bottom. The juice from the second carbonation flows through a holding tank, a cylindrical vessel with a central tube, which contains a propeller mixer. This mixer circulates the juice 20 times from the bottom to the top to mechanically remove from the juice the carbon dioxide liberated by the changing of the CO_3^{2-}–HCO_3^- equilibrium.

Control of Carbonations. The optimal end points of the first and second carbonations are determined experimentally. Addition of carbonation gas is controlled by continuous measurement of pH.

Second Sludge Separation. Since the amount of carbonation sludge obtained on filtration of the second carbonation slurry is only 2–5 % of that obtained on filtration of the first slurry (in cases where no calcium hydroxide is added in the second carbonation), slurry 2 is usually filtered directly through cloth- covered filters. Only in exceptional cases is it preseparated in decanters into clear juice and slurry concentrate. The sludge obtained is not "desweetened" in filters, but is either recirculated to the preliming stage or added to slurry concentrate 1, which is then filtered and desweetened.

Sulfitation. In some factories, the next stage is a so- called third carbonation. This comprises the treatment of the juice with gaseous sulfur dioxide to adjust the pH and brighten the color (prevention of excessive discoloration during subsequent evaporation). This step should be performed only if the pH of the thin juice is so high (pH > 9.2) that after evaporation (see Section 9) an alkaline thick juice (pH > 8.8) would be obtained. If the pH is not so high, it must be raised by the addition of soda (50–200 g per cubic meter of juice). The amount of SO_2 added should not exceed 50 g per cubic meter of juice. Otherwise, the pH of the juice can decrease sharply during evaporation, which causes corrosion. The exact amount of sulfur dioxide is usually added at the lowest point of a U-shaped pipe via a control valve. The SO_2 inlet pressure is kept constant by heating the SO_2 storage tank to a certain temperature (e.g., 30 °C $\triangleq$ 471 kPa).

Safety Filtration. If the thin juice is sulfurized, it must be filtered again before evaporation to remove precipitated calcium sulfite, which would otherwise result in strong scaling in the first stage of the evaporating station. Safety filtration is recommended, even in the absence of sulfitation. Tube filters that are precoated with a filter aid are an advantage. The level of turbidity (water-insoluble solids > 0.45 μm) of the filtered *thin juice 3* is less than 10 mg/L.

8.2. Other Juice Purification Processes

8.2.1. Simultaneous Defeco-Carbonation

Simultaneous defeco- carbonation refers to juice purification processes in which the raw juice, heated to 85–90 °C, is simultaneously treated with lime and carbon dioxide, while an exact or only slightly fluctuating pH value is maintained. In contrast to classical juice purification, in defeco- carbonation the colloids are precipitated in the presence of carbon dioxide in such a manner that the sludge particles are enmeshed immediately by calcium carbonate crystals. The

conglomerates thus formed are generally larger, better dewatered, and more solid than the sludge particles in classical juice purification. Therefore, the sedimentation and filtration properties of these sludge particles are very good. On the other hand, the resulting juices are only slightly thermostable because of incomplete destruction of invert sugar and low amide hydrolysis. They are stronlgy discolored in subsequent processing steps so that much darker thick juices are obtained.

Simultaneous defeco- carbonation is carried out according to the Dorr system, especially in the United States and the United Kingdom. The heated raw juice, together with six to eight times the amount of slurry, is first pumped into the bottom of a mixing vessel (primary tank), which is as large as the subsequent carbonation vessel. In the primary tank, a pH of ca. 10 is attained. Milk of lime (1.0–1.6 % CaO, juice based) is added as this juice mixture overflows into the actual carbonation vessel. Here, the juice is carbonated countercurrently to an optimal pH of 10.8–11.4. The finished juice is withdrawn from the bottom of the carbonation vessel. About six-sevenths of the juice is returned to the primary tank as circulated juice, and one-seventh proceeds to sludge separation. Further process steps correspond to those of classical juice purification.

8.2.2. Braunschweig Juice Purification

A further development of the Dorr system, the Braunschweig juice purification process, is used occasionally in Europe [116]. In addition to returning the slurry to the mixing vessel of the Dorr system, this process also requires the thick sludge to be recirculated to the raw juice in a separate mixing or reaction vessel located earlier in the process flow. Before carbonation at pH 10.8–11.2, the raw juice colloids pass through two separate pH steps during the thick sludge recycling (pH = 9) and the slurry recycling (pH = 10). Here, too, juices with very good sedimentation and filtration properties are obtained. The destruction of invert sugar, as in main liming, does not occur, which means that thermolabile juices are again obtained.

8.2.3. Defeco - Carbonation with Intermediate or Post Main Liming

The idea of combining the advantages of classical juice purification (attainment of thermostable juices that are free from invert sugar and have a good color) with the advantages of defeco- carbonation (good sedimentation and filtration properties of the precipitates produced) led to the development of other combination processes.

In the Braunschweig juice purification process (see Section 8.2.2), stabilization of the flocculated colloids is so good that defeco- carbonation for chemical stabilization of the juices can follow without impairing the filtration ability of the resulting carbonation slurry. For this reason, in one of the combination processes, before the separation of the precipitate, another addition of lime (main liming) to the slurry – which causes the pH of the juice to increase to > 12.5 for a certain time [117] – is carried out before a further carbonation step (pH 10.8–11.2).

In the *Novi-Sad juice purification process* (former Yugoslavia) [118], efforts are made first to flocculate the precipitable nonsugar substances in a type of defeco- carbonation; the precipitate is subsequently separated, and the juice is chemically stabilized in a main liming step. The lime is added as follows: 1.0–1.3 % of CaO is added in the defeco- carbonation, and 0.6–0.7 % of CaO (beet based) is used for chemical stabilization in the main liming step. The precipitate obtained after main liming in a normal first carbonation at pH 10.8–11.2 (i.e., mainly calcium carbonate) is separated with decanters. The resulting slurry concentrate (ca. 10–14 %, juice based) is returned to the defeco- carbonation. In this way, the entire sludge obtained can be filtered through one filtration unit [119].

9. Evaporation of Thin Juice

After purification, the thin juice has a solids content of 15–18 %. It is concentrated in a multistage process to a solids content of 68–74 % (thick juice), ca. 85–100 kg of water being evaporated per 100 kg of beets. From ca. 115–130 % (beet based) of thin juice, 25–30 % (beet based) of thick juice is obtained.

Table 7. Heat-transfer coefficients of juice (in W m^{-2} K^{-1}) as a function of total solids content

Solids range, wt %	Circulation evaporator	Falling-film evaporator	Plate evaporator
>15–25	2900–3500	2900–3500	3500–4000
>25–40	1700–2300	2300–3100	
>40–55	800–1400	1200–2300	
>55–65		800–1700	
>65	700–900	700–1000	1200–1600

Evaporated water accumulates as vapor condensate in the individual effects of the evaporator station. It contains about 6–10 $\mathrm{mmol/L}NH_4^+$, partly as $(NH_4)_2CO_3$, and varying amounts of steam-volatile organic substances [120]. The condensate is used as fresh water for extraction, as dissolving water in the sugarhouse (remelt, dilution of syrups, etc.), and as plant water for the wash and flume water cycles. The surplus must be treated biologically (see Section 6.8).

During evaporation, the juice generally undergoes only slight chemical alteration. The remaining glutamine is hydrolyzed primarily to pyrrolidonecarboxylic acid with elimination of ammonia. At the same time, the pH decreases (danger of sugar hydrolysis), and alkaline and oxidative decomposition of sugar occurs to a slight extent. Calcium salts of various acids (calcium oxalate, citrate, sulfate, and carbonate) precipitate, along with SiO_2 in some cases, due to the change in solubility conditions. To prevent the formation of scale on the evaporator tubes, calcium complexing agents (antiscaling) are added to the juice (5–10 g per cubic meter of juice). During juice evaporation, a dark color appears, owing to the formation of Maillard products [103] (condensation products from reducing carbohydrates and amino acids), Strecker degradation, and caramelization processes [103]. The discoloration [121] depends greatly on juice temperature (it should be $<$ 132 °C), H^+ activity, average residence time, and residence-time distribution.

Steam-heated evaporators of various designs (Robert evaporator, → Evaporation; falling-film, evaporator, → Evaporation; or plate evaporator) are used for juice evaporation. They have heating surfaces of normal or stainless steel tubes, that are smooth or twisted, up to 6000 m^2 per evaporator. A total heating surface of 2.0 to 2.5 m^2 is required for 1 t of processed beets per day.

The evaporators are arranged in multiple-effect evaporator stations in such a way that the saturated vapor generated in one effect is, in each case, used to heat the next effect and other heat consumers (cocurrent evaporation). The evaporator stations consist of four to six effects with a pressure drop from ca. 0.35 MPa in the calandria of the first effect to 0.12 MPa in the calandria of the last effect. In the process, the temperature of the juice falls from 130 °C to ca. 90–95 °C. The last effect operates under weak vacuum. The vacuum is produced by condensing the vapor with a 15–20-fold amount of water in jet condensers and by withdrawing the noncondensable gases (water-ring pumps, piston pumps). In industrialized countries, the heated water (condenser water) is recycled after cooling in cooling towers.

The heating surfaces must be distributed over the individual effects so that the desired thickening of the juice to 68–74 % solids content is achieved in the last effect. Also, the entire remaining saturated vapor requirement of the factory should be covered by vapor from the last two effects. The size of the heating surfaces in the individual effects must be calculated from case to case by taking into account the mass flow and the vapor consumption of the individual vapor users [122].

Guide values for the overall heat-transfer coefficient k (in W m^{-2} K^{-1}) for various solids contents in the case of rising and downflow evaporators are given in Table 7. The solids content, which correlates with the viscosity of the juice to be evaporated, greatly influences the heat transfer coefficient [121].

Because long average residence times and poor residence-time distributions in the individual evaporators are a disadvantage to the juice [strong discoloration, sugar destruction [123] up to 0.15 % (beet based)], efforts were made to decrease the entire installed heating surface by increasing the heat-transfer values or to reduce the residence time of the juice by using other evaporator designs (plate evaporator). Values for k of 7000–8000 W m^{-2} K^{-1} can be achieved for the

Figure 8. Rate of crystallization of sucrose as a function of supersaturation and temperature at different purities
A) Purity = 100 %; B) Purity = 80 %; C) Purity = 60 %

first effect and 2500 W m^{-2} K^{-1} for the second effect by increasing the juice velocity within the piping [e.g., by forced feeding (Buckau–Wolf continuous evaporator)]. Higher k values can be attained by using falling-film evaporators, and a smaller temperature difference is obtained between the calandria and the vapor space in the individual effects. As a result, the residence time of the juice is reduced by about half. This applies more to plate evaporators, the average residence time being reduced to 1–2 min per effect, which is only one-fifth that of a Robert evaporator station [124]. In 1992 an advantageous combination of plate evaporators and falling-film principle was introduced, and in the following years various integrated concepts were developed, with high k values and small heating surface, compared to other technology [125].

The steam requirement of the evaporator station and, therefore, the energy requirement for sugar production depend on the mode of operation of the factory. In the case of white sugar factories that do not produce refined sugar, the requirement is ca. 20–25 kg of normal steam per 100 kg of beets (54 000–67 000 kJ, corresponding to 15–18.5 kW · h). In factories with refined sugar production, this is increased by ca. 10 000 kJ, and in raw sugar factories, it is ca. 40 000 kJ. For the steam and energy economy of a sugar factory, see [126].

The precipitation and partial caking of sparingly soluble calcium compounds on the heating surfaces of the evaporators can greatly lower the heat-transfer and evaporating efficiency. In this case, the heating surfaces must be cleaned (boiled out). The equipment is treated first with a 3–5 % NaOH–Na_2CO_3 solution, then with a 3 % HCl solution containing an inhibitor, and finally with a 1–2 % Na_2CO_3 solution at the boiling temperature.

The heating surfaces of the evaporators that come in contact with the juice in the first and second effects are susceptible to corrosion. Corrosion occurs only occasionally, but to a very great extent. The causes of corrosion are disputed [127]. It is, in all probability, largely acid corrosion, which is favored by the fact that the oxide layers formed are constantly peeled off by the complexing agents (malic and citric acids) present in the juice. Acid corrosion can also be caused by the release of sulfur dioxide added to the thin juice in the vapor bubbles for a short time during evaporation. Alternatively, the metal may be attacked by an increased hydrogen-ion activity resulting from a decrease in pH of the juice by ca. 1.0–1.5 units at higher temperature [128]. Thus, the pH of thin juice should be kept high enough that the pH values of the thick juice do not fall below 8.8, measured at 20 °C. The thick juice is filtered before further processing.

10. Production of Sugar from Thick Juice

In the sugarhouse, sugar is produced from the thick juice obtained by the evaporation of thin juice. This involves crystallization (recovery of massecuite magmas) and separation of the sugar from the mother syrup (centrifugation). Both crystallization and separation of the sugar must be carried out in several steps because the technically achievable degree of desugarization in a single crystallization is limited by the maximum amount of crystals (50–60 % yield) in the magma (i.e., crystal mass) permitted for adequate movement and the increase in nonsugar substances in the mother syrup.

10.1. Production of Massecuite

From the thick juice (solids content = 68–74 %, sugar content = 61–70 %, nonsugar content = 4–7 %), multistage crystallization produces 85–92 % of crystalline sucrose without the use of ion-exchange processes or other molasses desugarization methods. The rest of the thick juice sugar (8–15 %) and practically all of the nonsugar substances in the thick juice are found in molasses, the mother syrup of the last crystallization (solids content = 84–89 %, sugar content = 50–56 %, nonsugar content = 32–40 %). If inclusion of mother syrup in the crystal and imperfections of the surface are prevented by optimal crystallization techniques, more than 99 % of all the ionogenic nonsugar substances and ca. 95 % of all the high molecular mass and surface-active nonsugar substances, including colorants, remain in the mother syrup after each crystallization step.

The syrups (thick juices, remelts) can be simplified regarded as three-component systems consisting of sugar, nonsugars, and water. If precipitation crystallization with organic solvents is disregarded, two methods are available theoretically for the industrial-scale crystallization of sucrose. Both methods are used in practice.

1) Evaporating crystallization (→ Evaporation, Chap. 6, → Evaporation, Chap. 7) is performed either isobarically or isothermally. With pure syrups, the sugar–water ratio in the mother syrup remains approximately constant during evaporating crystallization. With impure syrups ($p < 90$), however, this ratio increases because the amount of nonsugars in the mother syrup increases significantly during crystallization. Therefore, the solubility-increasing effect of the nonsugar substances also increases greatly. The solids content of the magma increases during evaporating crystallization.
2) Cooling crystallization is based on the decrease in solubility of sucrose with decreasing temperature (see Table 2). The remaining sucrose concentration in the mother syrup essentially follows the saturation line in the case of pure sugar solutions. In less pure industrial sugar solutions ($p < 85$, see Section 5), the solubility of sucrose in the mother syrup is considerably increased. In pure cooling crystallization, the solids content of the magma and the nonsugars–water ratio in the mother syrup remain constant. Cooling crystallization is used only in combination with evaporating crystallization.

Supersaturation Coefficient, Measurement, Control. The rate of cooling or evaporation during a crystallization process must be adjusted to the immediate crystallization rate (→ Crystallization and Precipitation, Chap. 4.2) to prevent secondary nucleation (→ Crystallization and Precipitation, Chap. 4.1.2) and achieve the most uniform crystal formation and distribution. The rate of crystal growth is controlled mainly by diffusion. The increase in mass of a crystal per unit time depends on the crystal surface [129]; the rate of insertion of the molecules into the crystal surface or the diffusion constant of sucrose in the solution [130]; the thickness of the diffusion boundary layer, which is between 60 and 150 µm [131]; and the supersaturation (Fig. 8). Mass transfer in the magma is influenced substantially by flow conditions [132] so that in evaporating crystallization, natural vapor-bubble mixing is supported by mechanical stirring [133].

The sucrose concentration is normally represented by the supersaturation coefficient c_1. This refers to the quotient

$$c_1 = \frac{c}{c^x}$$

where c is the sugar content of the solution in question and c^x the saturation concentration of sugar in the solution at the same temperature.

The range c_1 = 1.0–1.2 is called metastable. In this range, only crystals that are already present can grow; no new crystals can be formed. In the intermediate saturation range c_1 = 1.2–1.3, however, crystal formation can be caused by shock (air, impact, etc.). In the labile range above $c_1 \geq 1.3$, crystal nuclei are formed spontaneously. Maintaining the proper supersaturation coefficient is of great importance for practical crystallization. Since no direct method exists for continuous measurement of the supersaturation coefficient, it must be determined by indirect methods. The following parameters are suitable for this purpose: measurement of the electrical conductance, measurement of the boiling-point elevation, determination of viscosity or consistency [134], shifting of the oscillator circuit of radio-frequency sources [135] (frequency range 6–150 MHz), determination of the total solids content (e.g., radiometrically [136] or by high-frequency ultrasonic vibrations), and refractometric measurement of the solids content of the mother syrup [137]. Measurements of the viscosity or consistency of the magma (stirrability measurement [134]), total solids content of the magma [136], and density of the mother syrup have proved useful as guiding values for the entire crystallization process [137].

Attempts have been made to control crystallization via on-line measurement of the crystal-size distribution with the help of laser-diffraction spectrometers.

10.2. Evaporating Crystallization

Batchwise Process. Evaporating crystallization is carried out mostly batchwise in pans at 20–30 kPa and a massecuite temperature of 65–80 °C. The process can be divided into four sections [138]:

1) A quantity of syrup to be boiled is drawn into the pan so that the heating chamber remains covered during thickening of the syrup. The syrup is then evaporated to a supersaturation coefficient c_1 of 1.0–1.2.
2) A known number of crystals in the form of microcrystals (d' = 10–20 µm, $n \approx 2$, suspended in 2-propanol) or seed magma (d' = 180–250 µm, $n \approx 3.0$) are added to the syrup. The grain-size distribution of sugar crystals follows the Rosin–Rammler–Sperling distribution, n is a parameter of the Rosin–Rammler–Sperling distribution; high n indicates uniform grain size (→ Elutriation).

When working with microcrystals, the number of crystals added must be larger than the desired number of crystals in the entire massecuite in the pan at the end of sugar boiling. The reason for this is that part of the crystal nuclei dissolves because of the varying temperature and supersaturation conditions in individual tubing sections of the heating chamber. Table 8 lists the number of total surface of the crystals contained in 1 kg of sugar as a function of crystal size [139]. Until crystals become visible to the naked eye (interfacial length of ca. 50 µm), the supersaturation coefficient must be kept at about the same level. During this time, only small amounts of sugar crystallize, but the movement of massecuite must be maintained by means of water evaporation or mechanical stirring. For this reason, water instead of syrup is drawn into the pan in this phase. Since this type of "crystal seeding" results in a higher energy requirement, is technologically difficult to control, and is more time consuming, a seed magma has become the crystal seed of choice. This seed magma is produced separately by evaporating–cooling crystallization in a process similar to the one described here [140]. The mass of the crystal magma charge increases by a factor of 10^3 (30–50 kg of seed magma per tonne of massecuite in the pan). This mode of operation allows the use of feed syrups of higher concentration (e.g., thick juice and liquor with a solids content of 72–74 %; for details on liquor, see Section 13.2).

Table 8. Number and total surface area of crystals in 1 kg of sugar as a function of crystal size [119]

Size of crystals* L_s	Number of sugar crystals $N = 840 \times L_s^{-3}$	Total surface, m^2 $A_m = 4.21 \times L_s^{-1}$
0.2	105×10^6	21
0.4	13×10^6	11
0.6	3.9×10^6	7.0
0.8	1.6×10^6	5.3
1.2	0.49×10^6	3.5
1.5	0.25×10^6	2.8

* Mesh size of the screens in millimeters.

3) In the following phase, the crystals should grow to their final size without formation of new crystals (secondary nuclei) or conglomeration of the crystals present (agglomerated grain). To work at high supersaturations and, consequently, high rates of crystallization, the layer thickness λ (i.e., half the space between two crystals) must be less than 0.25 mm at the start and about 0.1 mm at the end of crystallization (layer thickness λ = volume of mother syrup in cubic meters per surface of sugar crystals in square meters). In addition, adequate circulation must be maintained within the massecuite in the pan. Therefore, natural vapor-bubble mixing is being increasingly supported by mechanical stirring [133]. The continuous or periodic feeding of juice and the rate of evaporation should be mutually adjusted in such a way that the requirements mentioned above are largely fulfilled. Control values here are indirect supersaturation measurements and the level in the pan.
4) Finally, the massecuite in the pan is concentrated to the proper consistency (crystal content 50–60 %) for centrifuge work. The solids content at the end of the crystallization process is 89–91 % in the case of "white" massecuites (refined massecuites, see Section 13.2, white sugar 2, raw sugar 1) and 92–96 % in the case of "brown" massecuites (i.e., raw sugar-2 and after-product massecuites, see Section 13.2).
The flowability of the magmas depends on the viscosity of the mother syrup (solids content, temperature, pH); crystal content; crystal-size distribution; and crystal form [141]. For this reason, only approximate values for the flowability of magmas can be given. The "viscosity" of refined massecuites is between 50 and 100 Pa · s, of white sugar massecuites between 90 and 170 Pa · s, of raw sugar-2 massecuites between 300 and 800 Pa · s, and of after-product massecuites between 500 and 2000 Pa · s. The end point of sugar boiling is determined by the consistency of the magma.

Despite batchwise operation, the technological course of the process is automated to a large extent [142]. A pan holds a maximum of 120 t of massecuite; the installed heating surface in square meters is about 45–60 % of the massecuite content in 100 kg (i.e., 200–300 m^2 calandria surface for a 50 t pan). The calandria are either tubular (brass or steel tubes with an inner diameter of 95 mm) or ring or hexagonally swaged calandria tubes with about 50 mm of clear space between two walls. To permit good circulation of the massecuite in the pan, a central tube is located in the middle of the calandria (e.g., for welded tubular and ring heating chambers), or an annular space is present at the outer edge e.g., for suspended calandria (dished floating calandria). In calandria with a central tube, additional circulation is possible via mechanical stirring. In this case, the massecuite is pushed through the central tube into the space below the calandria by a slowly operating mixer (60–80 rpm) [133]. The vacuum required (15–25 kPa) for boiling is produced as described in Chapter 9.

Continuous Process. Intensive efforts have enabled continuous evaporating crystallization to be developed into a controllable process on the condition that about 25 % of the seed magma (based on finished massecuite) produced batchwise is fed continuously into the process. New plants in industrialized countries, especially for "brown" massecuites (raw sugar 2, after-product), are installed as continuous plants [90, 129, 143].

Two types of equipment exist: horizontal and vertical. In *horizontal equipment*, the total crystallization distance can be divided without problem into several compartments (stirred-tank cascades, $n < 12$). With *vertical crystallizers*, a compromise must be made between the technological requirement for a good residence-time distribution (i.e., more than six compartments) and equipment costs. For this reason, vertical crystallizers usually consist of only four stirred tanks.

The individual process steps described above for batchwise crystallization are carried out one after another in a continuous process, spatially separated in individual compartments. This has both advantages and disadvantages. Thus, a crystal size distribution ($n > 3.0$) as good as that in batchwise operation has not yet been achieved because secondary crystal formation in individual compartments cannot be prevented. Unlike the batchwise process, secondary crystals cannot be redissolved, if necessary, by diluting the mother syrup (attainment of subsaturation) [144].

The advantages of continuous crystallization are as follows:

1) The temperature difference between heating steam and magma is smaller because the massecuite level is low, which makes use of low-pressure steam possible [145].
2) Individual compartments are easier to control. Continuous boiling equipment is usually operated isobarically. For vertical equipment, however, various vapor pressure steps are employed in individual chambers. In this way, evaporating–cooling crystallization is achieved (flash evaporation) [146].

Easy scaling of the equipment at the interface of magma–vapor space, especially in the case of white massecuites, is a problem that has not yet been solved [147].

10.3. Mixing of Massecuites and Cooling Crystallization

After the completion of evaporative crystallization, the massecuites are stirred continuously in mixers/crystallizers until the sugar is centrifuged off. This prevents separation of the crystal mass from the mother syrup by sedimentation. In mixing white massecuite, the temperature is usually held constant. Temperature changes, especially at the walls, must be avoided because of possible secondary nucleation and conglomerate formation.

Cooling Crystallization. Controlled cooling of the massecuite in the crystallizer during the mixing process (cooling crystallization) is generally employed for after-product massecuites (see Section 13.2) and is used only occasionally for raw sugar-2 and white sugar massecuites [148]. The advantages that can be achieved from a technological and heat economy point of view are so great that cooling crystallization will definitely be introduced in the near future for raw sugar-2 and white sugar massecuites [149].

In the case of after-product massecuites, about 85 % of the sugar crystal mass is produced by evaporating crystallization and the remainder by cooling crystallization. In cooling crystallization, the massecuite in the crystallizer is cooled by 0.5–1.5 °C/h from ca. 65 °C to 35–40 °C with constant stirring. This results in cooling crystallization times of 36–40 h. The crystallizers (→ Glucose and Glucose-Containing Syrups) used for cooling are horizontal U-shaped vessels or horizontal or vertical cylindrical vessels in which rotating or stationary cooling elements ($\approx$ 1.5–2.5 m^2/m^3 crystallizer volume) are installed. Thermostated water flows through these elements (temperature difference between the water and the massecuite in the crystallizer $<$ 15 °C). To lower the consistency, which increases with decreasing temperatures, water or syrup must be added to the massecuite during cooling in an amount that prevents the magma viscosity from rising above 3000 Pa · s.

An increase in consistency of the massecuite in the crystallizer can also be prevented by first cooling the massecuite only by 10–15 °C. Part of the massecuite (ca. 20 %) is then centrifuged. The centrifuged mother syrup is reheated, deaerated, and returned to the magma. In this manner, the crystal content of the magma is lowered by about 7 %. The crystal content increases again during further cooling, without the massecuite consistency increasing in an uncontrollable way. This mode of processing leads to a decrease in purity of 2–3 units in the molasses and, thus, higher sugar yields [150].

Cooling crystallization of other massecuites in the crystallizer, such as white sugar and raw sugar, is carried out in similarly designed crystallizers. Cooling rates up to 8 °C/h are possible, depending on product purity. The installed cooling surface per cubic meter of crystallizer volume is between 2.5 and 5 m^2. The temperature difference between cooling medium and massecuite in the crystallizer should not exceed 5 °C because of possible secondary nucleation at cooling surfaces.

10.4. Factors That Influence Rate of Crystallization

The rate of crystallization of sucrose is expressed as mass growth rate G (g m^{-2} min^{-1}) or as linear growth rate L_G (μm/min), both related by $G = 0.711 \times L_G$ [139]. The growth rate depends primarily on purity, temperature, and supersaturation (Fig. 8) [151]. Under otherwise identical

conditions, the rate is reduced by high molecular mass substances (e.g., dextrans), colored substances (e.g., Maillard products), and also by raffinose, kestoses, etc. [152]. A raffinose concentration greater than 1 % (based on magma solids) causes a marked decrease in the rate of crystallization and the formation of needle-shaped crystals, which is especially pronounced when calcium saccharate is returned to the juice purification (Steffen process, see page 50).

These problems can be avoided by cleavage of raffinose into sucrose and galactose with α-galactosidases [153]. Raffinose is usually cleaved in the raw sugar-2 green syrup. Attempts to eliminate the invertase contained, in addition to α-galactosidase, in the enzyme mixtures have been successful [154]. Apart from improving crystallization work, these processes permit better exhaustion of the molasses. However, the process is profitable only under certain conditions.

11. Separation of Sugar from Massecuite

Crystallized sugar is recovered from the massecuite mostly by batchwise centrifugation in screen-basket centrifugals [90] (top-suspended centrifuges, → Centrifuges, Filtering). This operation – including loading and unloading – is automated to such an extent that a station with several machines works practically continuously.

Continuously operated centrifuges, especially continuous conical basket centrifugals, are used only for centrifugation of after-product massecuites [156] and, to a lesser extent, for raw sugar-2 massecuites. In the raw sugar industry, pusher centrifugals are also used (→ Centrifuges, Filtering). Because of the crystal damage occurring in these centrifuges, they are only partly suited to centrifugation of consumption sugar (refined sugar, white sugar).

The first mother syrup obtained on centrifuging massecuite is called "green syrup." Molasses is obtained in the last crystallization step. For the theory of the formation and exhaustion of molasses, see [156].

If the sugar is subsequently washed in the centrifugal with hot water and steam to completely remove syrup particles adhering to the sugar crystals, a "wash syrup" is obtained. This washing is required in the production of consumption sugar (white, refined) and in the affination (washing the crystal surface free of mother syrup) of raw and after-product sugars (see Section 13.1). The wash syrup is generally collected separately. However, the wash syrup and the green syrup cannot be very cleanly separated. The separation technique was improved by introduction of a pneumatically controlled covering device in a BMA centrifugal [157]. Separation depends primarily on the purity that must be attained in the syrup to maintain the planned crystallization scheme. About 6–8 % (sugar based) of water and steam is required for washing. The water or steam wash must be started at the proper time to prevent unnecessary dissolution of sugar [158]. Before the actual washing process, washing the sugar crystals with slightly undersaturated sugar syrups of a higher temperature than that of the magma (syrup wash) to be centrifuged represents another measure to minimize the dissolution of sugar in the centrifuge.

Double- cone centrifugals are used today for the affination of brown massecuites, a syrup wash replacing the mixing process. This was previously a two-stage process (centrifugation of the mother syrup and remixing of the crystals in a syrup of higher purity than that of the original mother syrup; second centrifugation with washing of the crystals). In these centrifuges, the baskets of two continuous centrifuges are installed above each other (Fig. 9).

12. Preparation of Refined and White Sugar

Refined and white sugar leave the centrifuges with a water content of 0.5–1 %, depending on the temperature of the massecuite and wash water and the *g* attained (maximum 900) during spinning. Surface water content must be reduced to 0.03–0.05 % before further processing. For this purpose, hot-air heaters, cocurrently or countercurrently operating drum dryers (granulators), trickle-bed towers, turbo-tray dryers (→ Drying of Solid Materials, Chap. 2.1.2), or fluidized-bed dryers (→ Drying of Solid Materials) are used. The sugar can be cooled before it is discharged.

Figure 9. Double continuous centrifuge type SC 1350/1500 ODS

The next step is screening in vibrators or screening machines (→ Screening) in which the sugar crystals, lumps of > 2 mm, and fines of < 0.25 mm (which are redissolved to give remelt/liquor) are separated. In factories, all the preclassified sugar is stored in large- capacity silos without further separation or it is screened into individual fractions (e.g., size fractions 1.2–2 mm = coarse, 0.8–1.2 mm = medium, 0.25–0.8 mm = fine), and sometimes packed for sale.

In some cases, the medium-grain fraction is ground in a mill, and a 0.25–0.75-mm fraction is screened out (ground sugar). Coarse-grained sugar is used mainly in industry and fine-grained sugar is household sugar.

13. Working Schemes of Various Sugar Factories [149, 159]

Figures 10 and 11 present the crystallization and separation stages in beet sugar factories with different production programs. The starting material is thick juice of the same purity, solids con-

Figure 10. Crystallization schematic of a raw sugar factory with two-product operation (quantities in kilograms per 100 kg of beets)

Figure 11. Crystallization schematic of a white sugar factory (quantities in kilograms per 100 kg of beets)

tent, and mass in percent (beet based). For a better comparison, the sugar loss in the molasses was assumed to be the same in all variations. The total mass of massecuites to be processed and the mass of water to be theoretically evaporated are listed in Table 9 for different modes of operation. However, the water mass to be evaporated does not take into account the additional water utilized for crystallization (see Section 10.3) and the energy requirement for heating the media to be boiled.

Table 9. Total mass of massecuites processed and mass of water evaporated in various modes of operation*

Mode of operation	Amount of massecuite, kg/100 kg beets	Theoretical amount of water to be evaporated in the sugarhouse, kg/100 kg beets
Raw sugar factory with two-product operation (see Fig. 10)	≈28	≈7.5
White sugar factory with standard liquor process (see Fig. 11)	≈60	≈13.5
White sugar factory with 50 % refined sugar production	≈70	≈19.0
Sugar factory with 100 % refined sugar production	≈77	≈21.0

* The numbers change when other amounts of sugar or nonsugar enter the sugarhouse with the thick juice.

13.1. Operation of a Raw Sugar Factory

At first, beet sugar factories were all raw sugar factories, as are most cane sugar factories to this day. The raw sugar produced is processed further to white sugar in refineries.

In the refinery (see Section 13.4) raw sugar is again mixed with a mother syrup (p = 85–89, solids content 75 %) to give a magma, centrifuged, and washed with water and steam to obtain consumption (affinated) sugar as the immediate product. Alternatively, the affinated sugar is dissolved to give a remelt syrup and subsequently boiled to refined sugar.

Raw sugar factories are operated in accordance with the two-product scheme (Fig. 10). The raw sugar-1 massecuite in the pan is boiled from thick juice with the return of 15–20 % of raw sugar-1 green syrup (p = 78–80); the runoff syrup is drawn into the vacuum pan only at the end of the boiling process. At discharge, the solids content of the massecuite in the pan is 94 %, and the temperature is ca. 74 °C. The massecuite is cooled to 50–60 °C by stirring for several hours in mixers while more raw sugar-1 green syrup is added. The purity of the mother syrup is reduced from an initial 82–84 % to 78–80 %. In a second crystallization stage, after-product massecuite is made from raw sugar-1 green syrup that is not returned. After-product massecuite is separated into after-product and molasses.

The raw sugar (*raw sugar 1*: pol = 95–98°Z, organic nonsugar = 0.7–1.2 %, inorganic nonsugar = 0.8–1.0 %, water = 1–2 %; *after-product sugar*: pol = 90–92°Z, organic nonsugar = 3–4 %, inorganic nonsugar = 1.5–2.5 %, water = 2–3 %) obtained in a beet raw sugar factory has a light-yellow to dark-brown appearance because of the adhering syrup film. It must be made alkaline (prevention of inversion and formation of colorants) to be storable for longer periods.

Beet raw sugar is not suitable for consumption because of its unpleasant taste and its salt content. However, *cane raw sugar* (see Section 20.6) can be used directly in the production of gingerbread, fruit cake, etc., because of its aromatic flavor and taste components. Raw sugar has no nutritional physiological advantages over white sugar.

13.2. Operation of a White Sugar Factory – Standard Liquor Process

The schematic of crystallization of a white sugar factory operating according to the standard liquor process is shown in Figure 11. The white sugar-2 massecuite in the pan is made from thick juice by the addition of white sugar-2 wash syrup and remelt syrup (explained below) from affinated raw sugar 2. In some cases, the affinated raw or after-product sugar is dissolved directly in thick juice. Boiling a white sugar strike takes about 2–4 h. The crystal yield is 45–55 %, and the solids content at discharge is 90–92 %.

Remelt syrup (solids content = 68–72 %) is a solution obtained by dissolving affinated raw sugar 2 and after-product sugar (see below). It is purified of color and high molecular mass nonsugar substances ($p > 99.5$ %) by activated carbon or ion-exchange resins. This syrup is heated to 88–95 °C and filtered hot. Ceramic or cloth-

covered tube filters precoated with a filter aid (silica gel and cellulose) are used for filtration.

The raw sugar-2 massecuite in the pan is subsequently boiled from white sugar-2 green syrup (p = 87–89 %) and raw sugar-2 wash syrup (p = 85–88 %). In some cases, affinated or unaffinated after-product sugar is used as seed magma. In this case, "seed magma" refers to the after-product sugar suspended in diluted raw sugar-2 green syrup after heating and deaeration to give a massecuite in the crystallizer. Since the after-product sugar has an average crystal size (d' = 150–250 µm, n>3), the crystals introduced in this way grow further to 0.6–1.0 mm. Return of the after-product sugar as "seed magma" for the raw sugar-2 massecuite in the pan gives a raw sugar-2 product that has a more uniform grain size and, thus, can be affinated more easily. Return of unaffinated after-product sugar results in constant recycling of about 10–15 % of the entire nonsugar substances between after- and raw sugar-2 massecuite.

Raw sugar-2 massecuites in the pan are thickened to a solids content of 92–93 %, the boiling time being 3–6 h and the crystal yield 48–53 %. As mentioned above, the raw sugar 2 obtained is added directly to the white sugar boiling via the thick juice or in the form of remelt syrup.

From the green syrup of raw sugar-2 massecuite and the wash syrup of after-product massecuite, after-product massecuite in the pan is obtained, which has a boiling time of 10–20 h because of the low purity of the syrup to be boiled (p = 78–80 %) and the resulting low crystallization rate (ca. 700 mg of sugar per square meter of crystal surface per minute). If ion-exchange processes (see Section 14.2) are used to attain a better sugar yield, the raw sugar-2 green syrup must have a purity of $p < 75$ %. The solids content at discharge of the massecuite is 93.5–95.5 %; the purity in the mother syrup is 62–65 %, or 50–55 % if ion-exchange processes are used. As a result of subsequent cooling crystallization, the purity of the mother syrup, the molasses, decreases to 59–62 % or, if ion-exchange processes are used, 48–53 %. The crystal yield from after-product massecuites is 45–49 %.

After-product affination is shown in the scheme as if it occurs in the same centrifuge as separation of molasses. For the operation of affination, see Section 13.1. This additional process is one reason for returning the unaffinated after-product sugar as seed magma for raw sugar-2 massecuite in the pan (see above).

13.3. White Sugar Factories with a Refinery Scheme

In white sugar factories with the crystallization scheme of a refinery, all the thick juice obtained is first boiled to raw sugar 1. This eliminates any influences on quality exerted by the nature of the thick juice. The raw sugar is washed with only a little water and then (while raw sugar 2 is returned) dissolved to give a remelt syrup, from which the first refined-sugar massecuite is boiled. The resulting mother syrup yields a second refined-sugar massecuite.

The mother syrup of the second refined-sugar massecuite is, together with the wash syrup, processed to white sugar massecuite in the pan. The last two boiling stages correspond to those shown in Figure 11. Thus, it is possible to obtain 80 % of the white sugar production as refined sugar with five crystallization steps.

13.4. Refining

The working scheme of a refinery corresponds largely to that described above, the difference being that the raw material is "foreign raw sugar" instead of thick juice. The processing of *beet raw sugar* (see Section 13.1) involves only purification of the remelt syrup with the help of bone charcoal, activated carbon, and decolorizing resins before the boiling process. The processing of *cane raw sugar* (see Section 20.6) requires a chemical purification step because of the greater content of impurities (especially dextrans). For this purpose, the remelt syrup must be diluted to a solids content of 50–60 % and subjected to juice purification with either phosphoric acid–phosphates and CaO, or CaO and CO_2 (see Section 20.8).

14. Ion - Exchange Processes in the Sugar Industry [160]

Ion-exchange processes can be used to increase sugar yield or improve sugar quality (→ Ion

Exchangers, Chap. 12.1). As early as 1843, HOCHSTETTER proposed that alkali salts of the beet contribute to the formation of molasses. Because of these salts, ca. 11–15 % of the sugar introduced with the beet cannot be obtained in the crystalline state. For molasses formation and exhaustion, see [156]. At the turn of the century, efforts were made to increase sugar yield by exchanging alkali ions for less molasses-forming alkaline-earth ions with zeolites or other inorganic ion exchangers [161]. However, only after the development of ion exchangers based on synthetic resins were ion-exchange processes applied on a large scale.

Ion-exchange processes are used primarily for

1) Softening thin juices by exchanging alkaline-earth ions for alkali ions to prevent incrustation during evaporation
2) Increasing sugar yield by
   a) Replacing alkali ions of the raw sugar-2 green syrup by Mg ions (Quentin process)
   b) Chromatographic separation (→ Ion Exchangers) of molasses into sugar and nonsugar fraction
3) Decolorization of remelt syrups, thick and thin juices
4) Production of liquid sugar (see Section 15.8)

Ion-exchange resins used in the production process must comply with food regulations in different countries.

Processes used to increase sugar yield by removing ionogenic nonsugar substances (complete deionization) have not achieved importance.

When ion exchangers are applied in sucrose-containing solutions, the fact should be noted that strongly acidic cation exchangers in the H^+ form catalyze the hydrolysis of sucrose [162]. The total inversion (heterogeneous, homogeneous), in the case of a thin juice (solids content = 17 %, pol = 15.8°Z, p = 93.0 %) and a contact time of 4 min, is 0.07 % at 14 °C; 0.2 % at 17 °C; and 1.5 % at 23 °C (based on sucrose).

Monosaccharides (glucose, fructose, etc.) and reducing disaccharides are isomerized and, at high temperature, partly degraded to acids by strongly basic anion exchangers in the OH^- form [163].

14.1. Softening of Thin Juice

The ion-exchange process most frequently used in the sugar industry is the thin-juice softening process at 60–85 °C. Since the equivalent ratio (Ca^{2+}, Mg^{2+}) : (K^+, Na^+) in thin juices to be softened is ca. 1 : 15–1 : 25 – compared with, for example, 2 : 1 in water softening – only a small operating capacity (→ Ion Exchangers) is achieved (ca. 70–80 %). For removal of 1 kg of CaO from the juice, 7–11 kg of NaCl must be used as regenerant.

To avoid accumulation of regenerant wastewater, softening plants are sometimes regenerated with diluted raw sugar-2 green syrup containing ca. 1 mol/L alkali ions (Gryllus process [164]) or directly with 1 mol/L sodium hydroxide (Akzo process [165]), the regeneration runoff being returned in front of the first carbonation. Softening of thin juice with weak cation exchangers in the acidic form and regeneration of the exchangers with sulfuric acid [166] has developed to an important wastewater saving process, because the regeneration effluents can be used as a pressing aid in beet extraction and pulp pressing.

14.2. Exchange of Alkali Ions for Alkaline - Earth Ions

The sugar yield can be increased by 0.4 to 0.8 % (beet based) by exchanging 30–50 % of the alkali ions in the syrup for alkaline-earth ions. Since alkaline-earth salts are more hydrated per equivalent in aqueous sugar solutions than the corresponding alkali salts, they bind more water in the mother syrup of the last crystallization than alkali salts. Thus, less solution water is available for the sucrose. The molasses obtained after exchange can achieve a purity of less than 50 %, compared to 60 % for normal alkali molasses.

Quentin Process. The Quentin process [167] was used widely in the beet sugar industry as long as wastewater pollution was of lower importance compared to sugar yield. In this process, alkali ions in raw sugar-2 green syrup are replaced by magnesium ions. The runoff is diluted to a solids content of 68–70 % and passed at 85–90 °C over a strongly acidic cation

exchanger loaded with magnesium ions as counterion. Since only about 2–3 m^3 of runoff can be treated per cubic meter of resin in one operation cycle, the difficulty here is to "sweeten" (i.e., displace water from the resin bed with syrup) and "desweeten" (i.e., displace syrup from the resin bed with water) in such a way that the amounts of water used are just sufficient to dilute the runoff from 78 to 70 % solids content. Direct exchange of alkali ions for magnesium ions is possible in this case because the ionic concentration in the runoff is ca. 1 mol/L and the osmotic pressure in the surrounding liquid is very high. Consequently, the selectivity of the ion exchanger for divalent ions is largely counteracted. The exchanger is regenerated with dilute magnesium chloride solution.

14.3. Separation of Molasses into Sugar and Nonsugar Fractions (Ion Exclusion) [168]

At the same time as large-scale processes were developed for separation of glucose–fructose mixtures (invert sugar, HFCS, → Enzymes, Chap. 5.2.3.2.7), efforts were made to isolate sugar from molasses by using ion exclusion (→ Ion Exchangers). In 1994, several large-scale plants with a separation efficiency of 250 t of molasses per day were in operation (columns up to 3.0 m, separation path up to 32 m, batchwise or continuous, simulated moving-bed process, ion-exchange resin in Na^+ or Ca^{2+} form). The importance of the ion exclusion process has grown rapidly, and in 1997 about 80 % of the molasses in the US beet sugar industry were treated in this way [169].

Molasses diluted to a solids content of 60 % is separated at 80 °C into a sugar (solids content 20–30 %, p = 89–92 %) and a nonsugar fraction (solids content 4–6 %, $p < 20$ %) with water as the eluent. The fractions are evaporated in several stages to a solids content of 70 %. The sugar fraction is crystallized like thick juice, and the nonsugar fraction is processed as cattle feed.

Table 10 shows the extent to which individual classes of substances are divided among sugar and nonsugar fractions. With this process, up to 80 % of the molasses sugar can be obtained as white sugar, about 10 % goes into the nonsugar fraction, and the remaining 10 % is contained in the secondary molasses.

The overall sugar recovery was improved by introduction of the "Coupled Loop" separation [170] or the two-profile FAST technology [171]. Today (2005) equipment for separation of molasses into more than two fractions is being installed in the factories, and mainly betaine is isolated as a second fraction besides sugar [172].

14.4. Decolorization of Remelt Syrups and Thin Juices

Instead of treatment with activated carbon, remelt syrups and thin juices can be treated with strongly basic macroporous anion exchangers in the chloride form at 80–85 °C. The volume of remelt syrup treated in one operating cycle is 200–300 times the resin volume, depending on the purity of the solution to be decolorized. With a specific hourly load of 2–3 volumes of remelt syrup per volume of resin, an initial decolorization of 90 % is achieved; this is reduced to 50 % with increasing running time. The average decolorization attained is 75–80 %. Neutral or alkaline (pH 12–13) 10 % sodium chloride solutions are used to regenerate the ion exchanger. About 100–150 kg of NaCl is required per cubic meter of resin [173].

14.5. Elimination of Ionogenic Nonsugar Substances

Acidic Deionizing Process [174]. Thin juice (solids content = 15–17 %) cooled to at least 14 °C, or runoff or molasses diluted to 30–40 % solids content, is passed first over a strongly acidic cation exchanger in the H^+ form and then over a weakly basic anion exchanger in the OH^- form. The cations, amino acids, and betaine are adsorbed on the cation exchanger, and nitrogen-free anions and pyrrolidonecarboxylic acid on the anion exchanger.

To prevent ion slippage as far as possible, two pairs of ion exchangers are connected in series.

The acidic deionization process eliminates ca. 85 % of all nonsugar substances. Thin juices with a purity of 97–99 % are obtained. Sugar yield can be increased to a maximum of 1.2–1.4 % (beet based).

Table 10. Division of individual classes of substances between sugar and nonsugar fractions

Components	Molasses, %	Portion of Sugar fraction, %	Nonsugar fraction, %	Percentage going into nonsugar fraction
Solids	100.00	59.00	41.00	41.00
Sugar	60.00	54.50	5.50	9.20
Glucose	0.02	0.01	0.01	
Fructose	0.06	0.02	0.04	
Raffinose	2.50	0.45	2.05	82.00
Ash	12.50	1.10	11.40	92.00
Total nitrogen	2.60	0.30	2.30	88.00
Betaine	6.80	1.40	5.40	79.00
α-Amino-N	0.60	0.10	0.50	83.00

Apart from acidic deionization, other partial and complete deionization processes have been developed to prevent the hydrolysis of sucrose. These include the exchange of alkali ions for NH_4^+ ions plus the exchange of anions in the juice for HCO_3^-–CO_3^{2-} ions, and subsequent distillation of $(NH_4)_2CO_3$; or the exchange of anions for OH^- ions with a strongly basic exchanger, followed by elimination of alkali ions with a weakly acidic cation exchanger.

14.6. Production of Liquid Sugar [175]

Crystalline sugar is dissolved to give a syrup with a solids content of 50–60 %. The syrup is filtered through a depth filter (→ Filtration, Chap. 4), decolorized at 80 °C, and then deionized completely at 20–40 °C. For the production of invert sugar syrups, an inversion resin (cation exchanger in the H^+ form) is integrated into the deionization path. The desired degree of inversion is attained by variation of temperature and residence time.

The syrup leaving the ion-exchange facility is finally evaporated in several stages to a solids content of 65–75 %. Facilities are sized to require regeneration only after 120–150 h.

15. Production of Special Types of Sugar

15.1. Cube Sugar

The invention of cube sugar dates back to 1843. Today two different processes are applied in the production of cube sugar: the poured cube process (Adant process) and the pressed cube process.

Poured Cube Process. In the Adant process, the cube massecuite with a temperature of 98–100 °C is filled into the baskets of special centrifuges in which it solidifies on cooling (12 h) to give slabs. The baskets are then placed in centrifugals; the adhering green syrup is centrifuged off; the sugar slabs are washed with wash syrup (i.e., a saturated pure sugar solution) and centrifuged dry. Slabs containing 2–3 % moisture are dried in drying chambers or channels and then cut into strips with saw blades in special machines. Subsequently, the strips are broken into cubes in clipping machines and usually packed loose. Since cube yield is poor (ca. 80 % based on dried slabs) and production is both cumbersome and labor intensive (ca. 500 working minutes per tonne of cubes in large plants), poured cubes are seldom produced in industrialized countries.

Pressed (Molded) Cube Process. In the pressed (molded) cube process, crystal sugar with a certain grain size (e.g., 0.4–0.8 mm) and a relative density of 0.82–0.84 is moistened in a mixing screw with 1.5–1.8 % of water. It is subsequently pressed into cubes by means of presses (Machines Chambon, Paris [176]) or by vibration in vibration forming machines (SSA-Process) [177]. The individual cubes are dried in continuous drying ovens with hot air or on a steel band by high-frequency heating. They are then cooled and packed immediately in an arranged manner. The hardness of the cubes produced and, thus, their mechanical stability as well as rate of breakdown (dissolution) are substantially influenced by parameters such as grain-size distribution of the sugar used, water content in the mixing path, forming pressure, and drying rate [178].

15.2. Sugarloafs and Sugar Cones

Sugar cones (sugarloafs) have only regional and seasonal importance (burnt punch). Like cube sugar, they can be made by using the pouring or pressing process with a loaf or cone form instead of slabs. In the past, pressing was performed exclusively manually. Fully mechanical plants were developed in the 1960s [179].

15.3. Rock Candy

Rock candy is available as string candy or string-free candy. *String candy* is made according to the Stoven method. In this process, an especially pure sugar solution with a solids content of 75–78 % is discharged at 95 °C into tanks containing strings stretched across them. On cooling, the sugar crystallizes on the strings in large crystals. Cooling must occur very slowly (8–9 d) according to a definite temperature program. The "massecuite" should not be shaken during cooling. *String-free rock candy* can be made by crystallization in movement (e.g., in Wulff–Bock crystallizers) or in other continuous processes (e.g., where seed crystals are placed on screens) [180]. In all these processes, exact maintenance of temperature, flow rate, concentration, pH of the sugar solution, etc., is important. Brown rock candy is obtained by adding caramel sugar (see Section 15.9) to the sugar solution.

15.4. Icing Sugar

Icing sugar is made by grinding sugar in impact or hammer mills (→ Size Reduction). The grain-size distribution follows the Rosin–Rammler–Sperling distribution ($d' = 40$–60 µm, $n = 1.8$–2.5). Because of the danger of sugar dust explosion [181], icing sugar may be produced only if special safety measures are taken (separate rooms with light walls, ceiling, etc.). Icing sugar must be conditioned carefully (heated, dried to a certain moisture content, and cooled) before packing so that it does not become hard during storage. No general agreement exists about optimal conditioning requirements [182].

To prevent hardening of icing sugar, the addition of up to 5 % starch or 1.5 % anticaking agents, (e.g., certain calcium phosphates, magnesium carbonate, amorphous SiO_2) is permitted in many countries [183].

15.5. Instant Sugar

Instant sugar dissolves very quickly and is produced from finely ground icing sugar by agglomerating it in a fluidized bed with the addition of superheated steam [184]. The resulting granulate is fine pored and unevenly formed, and has a grain size up to 5 mm and a bulk density of 0.4 kg/L. In comparison, the bulk density of icing sugar is 0.6 kg/L and that of crystal sugar 0.8–0.9 kg/L, depending on grain size.

15.6. Preserving (Jelly) Sugar

Preserving (jelly) sugar is a preparation of crystal sugar, dry pectin, tartaric acid, and/or citric acid: 0.8–1.3 % pectin, depending on the jelling strength of pectin (→ Polysaccharides, Chap. 3.4.1), and 0.4–0.7 % tartaric acid or 0.6–0.9 % citric acid are added to the sugar. Pectin with a degree of esterification of 48–50 % dissolves completely in a solution with a solids content of > 50 % and forms a stable gel [185]. Amidated pectins (→ Polysaccharides, Chap. 3.4.1) are employed for the production of preserving (jelly) sugar, which contains sorbic acid as a preservative and is used in the proportions 1 part of preserving sugar to 2 parts of fruit.

15.7. Brown Sugar (Soft Sugar)

Brown sugar is the general term for crystal sugar that contains invert sugar (muscovado, brown candy, bastard sugar). This crystal sugar has color flavoring and taste components dissolved mainly in its syrup film (water content ≤ 3.5 %, total sugar content > 93 %, color in solution up to 30 000 ICUMSA units). Soft sugar is produced by directly boiling special sugar syrups, and the sugar centrifuged off is not washed. Alternatively, it can be made by mixing white crystal sugar with prepared sugar syrups [186].

VA = steam boiler- condenser; 1 B = vapor of the 1st step of evaporation.

15.8. Sugar Solutions

The quality, composition, and labeling of sugar solutions are regulated in the EC [187] and, in part, in the United States [188].

Accordingly, "liquid sugar" may not contain more than 3 %, "invert liquid sugar" not more than 50 %, and invert sugar syrup must contain more than 50 %, invert sugar.

Since liquid products can be transported and distributed easily, and because of their uniform quality from a microbiological viewpoint, sugar solutions are being used increasingly in manufacturing. Their share of the market, including high-fructose corn syrup (HFCS) (→ Glucose and Glucose-Containing Syrups, Chap. 6.2), is ca. 45 % of total sugar sales in the United States and 10–15 % in other industrialized countries.

In the production of sugar solutions, white sugar is dissolved in hot, low-salt drinking water; the syrup is filtered and sterilized by high-temperature, short-time heat treatment (8 s at 138 °C). The syrup is then cooled to 15–20 °C and stored almost sterile (plate counts < 200/10 g dry substance) before transport. Any contamination with microorganisms in the air must be avoided.

Solutions containing invert sugar are prepared mainly by the ion-exchange process (see Section 14.5). However, batchwise or continuous *acid hydrolysis* is also used [189]. On heating to 85 °C and acidification with sulfuric acid to pH 2.5 (ca. 140 g of sulfuric acid per 100 kg of sugar solution), an 80 % sucrose solution undergoes inversion to ca. 70 % in ca. 90 min. To prevent further inversion, the pH must be increased subsequently with sodium carbonate (pH 4–5). If no further discoloration is to take place, the inverted solution should be cooled quickly. *Enzymatic hydrolysis* of concentrated sugar solutions with the help of immobilized invertases at their pH optimum of 4.5 (β-fructosidase, E.C. 3.2.1.26) is technically possible, but it is economically inferior to the other processes. Inverted sugar solutions are supplied with a solids

content up to 75 %. The degree of inversion must be ca. 0.65 to prevent crystallization of glucose or sucrose.

15.9. Burnt Sugar and Caramel Colors (Caramels)

Burnt sugar is made by heating (melting) sugar or sugar solutions. It has a typical caramel taste, which deteriorates with increasing color of the product. Burnt sugar is produced with a color of up to 18 000 EBC (European brewery colour) units, the caramel taste determining the product's value [190]. *Caramel colors* (caramels) are made from sugar or other edible types of sugar by adding certain permitted burning additives [191]. Caramels can be divided into four groups: caustic, alkali sulfite, ammoniac, and ammonium sulfite [192]. Different types of caramel are required to color certain foods (e.g., spirits, vinegar, malt beer, and cola beverages).

16. Storage of White Sugar

Since white sugar factories produce sugar only during the working season (three to six months per year), but sugar is consumed year-round, large amounts of the sugar produced must be stored. Consumption sugar is packed in 100-kg jute sacks or in 50-kg (25-kg) paper sacks and stored. Household sugar is packed in the factory directly in small packages of 0.5–5 kg.

Sugar should not contain dust or lumps before storage. It must be dried to 0.03–0.04 % residual moisture and cooled to 20–25 °C. Storage in high-capacity silos is becoming increasingly common [193] because it enables the delivery of bulk shipments (rail/trucks) to the manufacturing industry. In industrialized countries, industry consumes approximately two-thirds of the total sugar sold.

White sugar silos are usually vertical cylinders made of steel, prestressed concrete, or sheet steel and provided with a heatable insulated jacket [194]. Most of the silos have a capacity of 10 000–40 000 t, a diameter of 20–37 m, and a sugar head up to 40 m high, but very large silos with capacities of 80 000 t, diameters of 51 m, and a sugar head up to 60 m high were erected in 2000 [195]. Sugar silos are filled and emptied according to various principles; e.g., they are filled from the bottom upward from a central pipe with a screw system and emptied from the top downward (N. Weibull, Malmö; ABR, Wiedemann, Sarstedt). In other silos, sugar falls through the entire free height of the silo. Measurements have shown that fears of dust explosions in this mode of operation (due to sugar dust concentrations) are unjustified [181, 196]. The sugar stored in a silo of this type can be circulated constantly by removing it from the bottom and transporting it to the top. This measure, together with proper air conditioning ($T < 25$ °C, R.H. < 60 %) of the silo, prevents sugar from caking and/or binding during storage. For air conditioning and especially for adjusting the humidity, adsorption and refrigeration processes are used.

During storage, sugar releases not only moisture adhering as a syrupy film to the crystal surface, but also part of the bound moisture (in the mother syrup enclosed in crystal defects) [197].

High-capacity silos constructed like sugar silos are used for storage of pelleted dry pulp (see Section 17.2) [198].

17. Auxiliary Facilities in a Sugar Factory

17.1. Steam and Energy Balance

The steam requirement of a sugar factory is met by the production of superheated steam in boilers of various types. High-pressure boilers (6.7–10 MPa) are being used increasingly. All or the largest part of the superheated steam (<537 °C) is expanded to 0.25–0.30 MPa via turbogenerators (counterpressure machines). The electrical energy thus produced is largely consumed in the sugar factory itself, and the surplus is transferred to the public grid.

Unlike the process steam requirement, the electrical energy requirement has increased in the last years. Consequently, gas turbines are now set up in front of the boiler plant to meet electrical energy requirements.

The steam flow, vapor distribution, and condensate scheme for a white sugar factory are depicted in Figure 12. The entire condensate from the first effect of the evaporator station (b) (steam condensate from the turbines) is used

as boiler feedwater. In the case of low-pressure boilers (<4 MPa), condensate from the second effect of the evaporator station is used to cover losses. However, since this condensate can contain volatile organic substances [120] and, possibly, traces of sugar, this portion of the water is replaced by treated water in the case of high-pressure boilers.

Exploitation of the energy of boiler exit gases for drying cossettes in the beet sugar factory did not gain acceptance for decades. Only with the introduction of oil or gas burners was boiler exit gas at 150–200 °C increasingly used as "additional air" for drying pulp. In this mode of operation, the oil or gas is burned with a slight excess of air, and the 1600 °C hot burner gases are cooled subsequently with boiler exit gas to the required working temperature of the drying process (600–700 °C).

Herewith, 93–94 % of the usable amount of heat introduced with the fuel can be utilized, compared to 80–86 % in the normal mode of operation. For detailed energy balances of the entire factory, see [126].

In contrast to beet sugar factories, which must use fossil fuels for steam generation, the entire energy requirement of the *cane sugar industry* is met by burning the bagasse in specially constructed boilers (see Section 20.5.3). Since the cane industry has taken over time-tested heat-flow schemes for the production process from the beet sugar industry, a surplus of bagasse is now available that can be used elsewhere.

17.2. Drying, Pelletizing, and Storing Pulp

Drying. Good mechanical pressing of the extracted pulp is a precondition for efficient pulp drying (see Section 7.5). If 5.6 kg of dry pulp (solids content 90 %) is obtained from 100 kg of beets, the amounts of water listed in Table 11 must be evaporated during drying.

The amount of heat required for evaporation of 1 kg of water depends on the temperature gradient between the entrance and exit of the drum. The higher the combustion gas temperature at the entrance of the drum, the greater is the thermal efficiency of the plant. However, excessively high entrance temperatures lead to strong scaling of the internals and burning of the material to be dried [formation of volatile organic acids, total amount expressed as total organic carbon (TOC) and CO]. For entrance temperatures of 600 °C, ca. 3500 kJ per kilogram of water to be evaporated must be employed. In the drums, 150–180 kg of water evaporates per hour per cubic meter of drum contents [199]. Cocurrently operated rotary drum dryers with preceding firing are used for drying pressed pulp (→ Drying of Solid Materials). For measures for the efficient use of energy in cossette drying and optimal control of cossette drying plants, see [126, 200].

For predrying pressed pulp, low-temperature dryers have been employed to make use of the lower-energy heat that was previously released to the environment. Most of the four-rack belt dryers operate with hot air (≈ 60 °C), which is heated with the waste heat carriers' hot water and condensate (< 70 °C) [201].

Apart from hot-air dryers, steam dryers are now being used to dry pressed pulp. Drying is achieved with superheated steam:

1) With steam of 130 °C, which expands to 102–103 °C (≈0.1 MPa) by the uptake of water [202] or
2) With steam of 260 °C (ca. 2.6 MPa), which expands to 148 °C (0.37 MPa) [203]

The advantages of steam dryers are energy saving and the closed design, which prevents escape of gaseous emissions (odors). Besides high investment, improvable performance and considerable maintenance costs have to be taken into account as disadvantages [204].

Processes that eliminate water from pressed pulp not by drying, but by multiple-effect evaporation with the help of an entrainer (e.g., edible oil, paraffin oil) have not yet gained acceptance (Carver–Greenfield process).

Storage and Transportation. Dried pulp has a bulk density of 200–300 kg/m^3. Thus, storage and transportation of this material are very space consuming. Also, in this form, it is not flowable, is poorly miscible (with other components in the production of mixed feed), and only poorly grindable. For these reasons, dried pulp is for the most part pelletized (8–10-mm diameter, 20–30-mm length) [205] (→ Size Enlargement B, D). This increases the bulk density to 650–700 kg/m^3, and the product can

Table 11. Amount of water (in kilograms) to be evaporated in the drying of beet pulp as a function of solids content of pressed pulp

	Solids content of pressed pulp, %										
	16	**18**	**20**	**22**	**24**	**26**	**28**	**30**	**32**	**34**	**36**

be handled and ground easily. Dried-pulp pellets are stored in warehouses and, more recently, in high-capacity silos of up to 30 000 t [198]. In these silos, better conditioning of the entire space is possible and molding is virtually impossible.

17.3. Lime–Carbon Dioxide

For juice purification, 0.8–2.0 % (beet based) of CaO and 4.0 % (beet based) of carbonation gas (carbon dioxide content of 42 vol %) are required. These materials are produced in the sugar factory itself by burning limestone (2–5 %, beet based) in high-performance shaft kilns [206]. The quicklime is hydrated with water to form milk of lime (180–220 g of CaO per liter of water) and freed of oversize material by means of vibrating screens, rake classifiers, and hydrocyclones. To guarantee exact dosing, the density of the milk of lime is kept constant. Since the lime added during juice purification is fully retained in the carbonation sludge (see page 26) and is largely present as calcium carbonate, efforts have been made to completely or partially reburn the carbonation sludge.

On addition of 1.5 % of CaO (beet based), the following average composition of the carbonation sludge (solids based) can be expected: 48–50 % CaO, 0.9–1.2 % MgO, 0.3 % K_2O and Na_2O, 1.7–2.1 % PO_4^{3-}–SO_4^{2-}, 23–26 % CO_2, 2–5 % SiO_2 (sand, clay), and 10–15 % organic substances (protein, pectins, polysaccharides, citric, oxalic, and malic acids, etc.). Depending on the conditions of recalcination (temperature and residence time), decomposition of the clay or sandlike components to soluble calcium aluminates and calcium silicates can occur. This greatly reduces the quality of the reburnt lime [207]. After reburning once, 50–55 % of the dry sludge weight is recovered, and after repeated reburning, a strong enrichment of MgO, calcium aluminate, silicate, calcium phosphate, and calcium sulfate occurs so that part of the carbonation sludge must be discarded. In the United States, a rotary kiln and a circular multiple hearth furnace have been used for many years for reburning carbonation sludge [208]. Attempts have been made on a pilot scale to recalcine previously granulated carbonation lime cake [207] with a fluidized-bed system and with a high-velocity reaction chamber [209], which can process the carbonation lime in its primary particle-size distribution ($d' < 10$ µm).

Carbonation Lime Cake as Lime Fertilizer. In the past, naturally dried carbonation sludge was spread manually on fields by farmers to improve the soil structure of acidic soil. Today, only carbonation lime cake that can be spread on the ground by machines is sold. For isolation, see page 26. The composition is given in Table 12 [210].

Table 12. Fertilizer analysis of carbonation lime cake with 60–70 % solids content* (in kg/1000 kg) [210]

Nutrients	Average	Variation
Basic components calculated as $CaCO_3$	500	460–540
Organic substances	100	80–150 (180)
Total N	4	3–6

K_2O	1	0.2–2
MgO	10	5–13 (22)

* Other constituents ca 1 kg sulfur, 1 kg sodium, and 0.9 kg boron.

18. Desugarization of Molasses

To reduce losses of sugar in molasses, chemical processes are used that are based on the fact that sucrose forms poorly soluble compounds (saccharates) with alkaline-earth hydroxides under certain conditions. The structure of these saccharates is still not understood clearly. Of the methods used (Strontian process, baryte process, Steffen process) [211], only the *Steffen process* is still important. It is used on a large scale in the United States, the CIS, Turkey, and Iran.

Steffen Process. This process can be operated batchwise or continuously [212], at ca.

10 °C (cold) or 65–80 °C (hot). If operated carefully, ca. 40 kg of white sugar can be produced from 80 kg of molasses solids.

The molasses is diluted (e.g., to a solids content of 10–15 %) and cooled to 10–14 °C. At this temperature, very finely ground CaO (<100 µm) is added slowly, with continuous stirring, until 0.7–0.9 % of free CaO is present in the solution. The precipitated tricalcium saccharate ($C_{12}H_{22}O_{11} \cdot 3\ CaO$) is filtered off with filter presses or belt filters, washed with water, and suspended in water. The filtrate containing the nonsugar substances in molasses (Steffens waste) can be used for isolation of glutamic acid, betaine, raffinose, etc., or evaporated to give vinasse (see Section 22.3). During the beet processing season, the tricalcium saccharate suspension is used instead of part of the lime milk as the precipitating agent for juice purification. Outside the working season, the tricalcium saccharate suspension is heated and calcium hydroxide is precipitated as calcium carbonate by the introduction of CO_2. The sugar solution thus obtained is subsequently evaporated and boiled.

Apart from the Steffen process, chromatographic processes are being used on a large scale for the desugarization of molasses (see Section 14.3).

Membrane and electrodialysis processes, also with ion-exchange membranes, have not gained acceptance because of the short service life of the membranes used [213].

Isolation of Glutamic Acid, Betaine, Raffinose, and Other Substances. Of all the nonsugar substances present in sugar beet, the substances mentioned above are isolated on an industrial scale. *Glutamic acid* is isolated from the spent wash from molasses desugarization processes, especially from Steffen waste (after hydrolysis of L-pyrrolidonecarboxylic acid); from the regeneration wash from deionization processes; or from the nonsugar fraction in the chromatographic separation of molasses (see Section 14.3). Processes for isolating amino acids are described in [214].

Like glutamic acid, *betaine* [215] can also be isolated from molasses on an industrial scale, today preferentially by chromatographic separation [172]. *Raffinose* [216], *inosite* [216], *galactinol,* and *kestoses* can be isolated from molasses by chromatographic separation as well.

19. Sugar Yield, Energy Requirements, Processing Aids, Water, and Working Time

The *sugar yield* is very important for the profitability of a sugar factory. In a modern mode of operation (continuous extraction process, good juice purification and crystallization) with exact operation control, the sugar losses occurring in a white sugar factory are listed in Table 13.

Table 13. Sugar losses in a white sugar factory (kg sugar per 100 kg beets)

Type of loss	Portion of sugar lost	Sugar contained in side products
Respiration loss during storage (average of 8 d) between harvesting and processing	0.12–0.20	
Losses during fluming and washing	0.10–0.25	
Extraction losses in pressed pulp		0.20–0.30
Unaccounted losses*	0.15–0.40	
Losses in molasses		1.6–2.1
Average total losses	0.6	2.1

* Sucrose losses due to bacterial activity, sucrose destruction during juice purification, evaporation, and boiling.

If the beets have a sugar content of 16.0–17.5 %, 13.3–14.6 kg of white sugar is obtained per 100 kg of beets. Since the amount of accounted and unaccounted losses does not vary greatly, the sugar yield depends primarily on the sugar content of the beets.

The sugar yield can be increased by 0.3–1.5 kg per 100 kg of beets by the use of ion-exchange or molasses desugarization processes.

The *primary energy* required for the boiler house (i.e., only for sugar production) is 20–25 kW · h per 100 kg of beets and for cossette drying, 2–3 kW · h per 100 kg of beets. Since the 1970s, the total primary energy consumption in the European sugar industry has decreased by more than 50 %.

Limestone consumption is about 2–5 % (beet based), and the coke requirement for burning limestone is 7–10 kg per 100 kg of limestone.

Other processing aids employed include acids (sulfuric, hydrochloric, SO_2), hardening agents (calcium sulfate, calcium chloride), disinfectants (formalin, hydrogen peroxide), antifoaming agents, antiscaling agents, activated carbon, and filter aids.

Theoretically, a sugar factory requires no additional water supply from ground or surface water because with the sugar beets, 0.75 m^3 of water is fed per tonne of beets into the production process as condensate and ca. 0.35–0.45 m^3 of water is required per tonne of beets for supplementing the water cycles (0.25–0.3 m^3 per tonne of beets for the flume water cycle, 0.1–0.15 m^3 per tonne of beets for evaporation water losses in the cooling water cycle). Wastewater from the flume water cycle and surplus condensate are treated biologically before they enter the wastewater receiving stream.

In practice, however, at the start of the working season the water cycles must be filled with ground or surface water.

To process 1 t of beets, including delivery and unloading of beets and storage of the sugar in silos, 10 working minutes are required during the working season, depending on the size, mechanization, and automation of the factory. On the other hand, the total work requirement per year amounts to 30–40 working minutes, including the time required for packing and dispatching, plant maintenance and repair, and general administration.

20. Cane Sugar

Production and consumption figures for cane sugar are provided in Tables 1 (Section 2.1) and 18 (Chap. 23).

20.1. Sugarcane Cultivation

Sugarcane is a giant tropical grass; *Saccharum officinarum,* the cane of commerce, is a complex hybrid of several *Saccharum* species. Constant development of new varieties through crossbreeding and selection is essential to maintain disease resistance and healthy crops with high sucrose content. Seed crossings (bi- or poly-) produce multiple interspecies varieties; selection takes place over eight to twelve years. Somoclonal variation in sugarcane has prevented replication by tissue culture; the varieties selected are increased by vegetative reproduction. The same procedure is employed in cane planting: a section of stalk with one or more buds (each node has at least one bud) is planted; roots develop; then a shoot appears. Cane is planted, manually or mechanically, in single or multiple rows, in furrows, and covered with soil. Planting season and fertilizer, pesticide, and growth regulator applications vary tremendously from the subtropical areas (Louisiana, Pakistan, Morocco) to the optimum growing tropical areas (North Queensland, Colombia, Cuba). Generally, replanting is not necessary after each harvest: buds on the plant base and roots remaining will sprout again to produce another crop, called *ratoon* or *stubble*; this ratooning is repeated until the yearly decline in yield (successive ratoons yield lower cane tonnage) is no longer economical. Ratoon crops vary from none in Hawaii, where push-rake harvesters can harvest roots with the stalks, to eight to ten in optimum regions: two to four ratoon crops are customary.

Cane pests include insects (borers, leaf hoppers, grubs, aphids) and vertebrates (rats, pigs, and elephants), which eat and trample cane. Other *diseases,* now often controlled by breeding, include mosaic, rust, smut, and ratoon stunting disease. The most common *weeds* are other grasses and therefore difficult to control with herbicides.

Sugarcane is the most efficient collector of solar energy in the plant kingdom, converting 2 % of available solar energy into chemical bonds of stored compounds, chief among them sucrose. Yield in tonnes of cane per hectare varies from 55–60 t in poor growing areas to more than 200 t for cane grown for 18–24 months in optimum areas (e.g., Hawaii). The quantity of sugar produced per hectare varies from ca. 5.0 t (Ethiopia) to ca. 26 t (Campos, Brazil).

Harvest season is generally during the cooler, drier part of the year, varying from three months (October–December) in Louisiana, to the first half of the year in most Northern Hemisphere tropics and the second half in most Southern Hemisphere tropics, to year-round in Hawaii, Colombia, and Peru.

20.2. Composition of Sugarcane

Sugarcane stalks, the portion of the plant desirable for milling, contain 73–76 wt % water and 24–27 wt % solids (10–16 wt % soluble solids, 11–16 wt % dry fiber); the inclusion of "trash"

(trash is defined as leaves, tops, roots, weeds, soil, and other extraneous matter) will increase the total solids level but decrease the sugar content of the mass, and thereby of the cane juice. The sugar (sucrose) content per tonne of cane varies from 75 kg in marginal growing areas or with overratooned or diseased cane, to more than 140 kg in very good quality cane.

The soluble solids content (in percent) in the juice is listed as follows [7]:

Sugars	75–92
Sucrose	70–88
Glucose	2–4
Fructose	2–4
Salts	3.0–4.5
of inorganic acids	1.5–4.5
of organic acids	1.0–3.0
Organic acids	1.5–5.5
Carboxylic acids	1.1–3.0
Amino acids	0.5–2.5
Other organic nonsugars	
Protein	0.5–0.6
Starch	0.001–0.050
Gums	0.30–0.60
Waxes, fats, phosphatides	0.05–0.15
Other	3.0–5.0

The major amino acids are aspartic and glutamic acids; the major inorganic salts are chlorides and sulfates of potassium, calcium, and magnesium. The level of invert sugar decreases as sugarcane matures, but increases at the expense of sucrose concentration after cane is cut (or wounded), with a concomitant decrease in pH.

Concentration of nonsugars relative to sucrose, or juice purity (see Section 5), affects the potential isolation of sucrose: in general, higher nonsugar levels or lower purity make sucrose recovery difficult and decrease yield.

Sugarcane fiber makes up 10–17 wt % of millable sugarcane. Called bagasse after the milling stage, cane fiber has three components: (1) inner stalk pith (containing most of the juice); (2) fiber in the outer stalk and small fiber bundles in pith; and (3) nonfibrous, wax-coated epidermis, in the ratio 6 : 13 : 1. Bagasse is composed of cellulose (40–60 %), hemicelluloses, especially L-xylan (20–30 %), and lignin (15–21 %) [14].

20.3. Deterioration of Sugarcane

The composition of sugarcane after it is cut (harvested) or wounded by freeze or pest damage can change drastically and rapidly. "Stale cane is an anathema to the whole industry: growers lose tonnage and processors lose sugar" [217]. Deterioration is both chemical and microbial: chemical deterioration includes hydrolysis of sucrose by invertases; the invert sugar formed continues to decompose partly during juice purification to colorants and acids, which lower the pH of the juice and increase inversion. Degradation (and sugar loss) by microorganisms invading open cane tissue includes *yeast* infection (causing production of ethanol, lactic, and acetic acids) and *bacterial* infection, especially from *Leuconostoc mesenteroides,* which converts sucrose to dextrans (long-chain polymers of glucose) and organic acids [218, 219]. If present in juice at concentrations >1000 mg/kg, dextrans can increase viscosity of juices and syrups; hinder clarification, filtration, crystallization, and centrifugation; and lower sugar yield [7, 14, 220]. The deterioration rate increases with temperature, mud on cane, and time. Deterioration, which varies in rate with variety, can best be controlled by minimizing cut-to-crush time (see Section 20.4) and processing frozen cane as rapidly as possible. Bactericide application is not practical in fields or cane yards; treatment in the factory, to control further dextran formation, with the few approved biocides has proved too expensive and impractical [220]. Clearing with steam or very hot water spraying of equipment is the recommended factory treatment.

20.4. Harvesting and Delivery

Harvesting. More than 60 % of the world's sugarcane is harvested *by hand* in the tropics, where labor is available and employment is desirable. Cane knives range from long machetes to shorter-handled Australian and Brazilian knives with hand guards. Cane leaves and tops – which contain little sugar, add weight to transport, hinder cane cutters, and wear down mill rolls – are removed first by burning the cane field and then by hand or mechanical harvesters. Cane stalks are sufficiently high in moisture so that controlled and rapid burns (fire in a 50-ha field will be complete in 3 min) incinerate only the leaves, tops, and trash. In Australia and Hawaii, cane is harvested without burning, to

Figure 13. Constant-ratio cane mill with pressure feeder combination

provide more fiber as fuel (for electricity cogeneration at the factory) and for environmental protection [221]. Important factors in cutting are to produce clean, undamaged cane, free of trash, and to leave viable root stock in the field. *Mechanical harvesting* is found in Australia, the United States, some Caribbean and Latin American Countries, and new developing cane areas in Southeast Asia. Most common are *combine harvesters*, or chopper harvesters, developed in Australia, which cut cane stalks at the base, cut the stalk into billets [9 to 15 inches (i.e., 28–38 cm) long], blow excess leaves and trash off the billets, and drop the billets into a cane cart pulled alongside the combine harvester. In Louisiana, or where tonnage is light, *soldier harvesters* cut and top erect cane, leaving rows of whole stalks in the field, which are burnt after harvest because the canopy is too light to support a burn on standing cane. Other whole-stalk harvesters in Hawaii, where cane tonnage is heaviest, are the *V-cutter,* which cuts cane at base but not at top, and the *push-rake*, which pushes cane, including the roots, out of the ground (used on hilly areas), necessitating replanting. Under good conditions, a man can cut 0.5 t of cane per hour, and a combine harvester 30 t of cane per hour, with other mechanical systems between 15 and 30 t/h. Mechanical cutting is always more expensive than hand cutting and yields lower quality, more damaged cane and an increased portion of trash, but is increasing for sociological reasons.

Transportation. Cane *loading* in the field is accomplished by hand, grab loaders, or continuous belt loaders, into small bins or wagons, which collect at transloader stations for transfer to larger transport containers. In some areas (India, Pakistan, Southeast Asia, Africa), cane is still transported in small bullock carts. Transport by narrow gauge railroad (cheapest) continues in Australia and the Philippines; by water, in China, Southeast Asia, and Guyana; and by road, elsewhere. Chopper-harvested cane must

be shipped directly to the mill and be processed on arrival, not stored in the mill yard, to prevent serious deterioration: delivery time of less than 24 h is recommended [220].

Harvesting and shipping schedules are decided between grower and processor to ensure a constant supply of cane for the mill, and a fair distribution of maturity and quality.

Cane payment is generally based on weight, with a deduction for trash. Where payment for cane quality (weight, sucrose content, fiber, sugar yield) has been introduced (United States, South Africa, Australia, Brazil, Colombia, Philippines), the quality and efficiency of the industry have greatly improved [222].

20.5. Sugarcane Processing: Milling and Diffusion

Cane that arrives at the factory (or mill, Central, Ingenio, or sugarhouse) is either processed directly or stored temporarily (preferably <12 h) in the factory yard. Because factories operate 24 h but transport is only by day, cane is stored in delivery vehicles or piles in the factory yard for nighttime grinding. Hygiene and prompt use are important for good sugar yields. The cane is then loaded onto a moving table to enter the factory. Sugarcane factories generally run during the entire harvest season, shutting down temporarily only to clean out evaporators (see Section 20.5). Hawaiian and Australian factories close on weekends. Factories range in size from 300–400 t of cane per day (tcd) in some less developed areas, through the usual range of 4000–10 000 tcd, to the large Florida factories of 20 000–25 000 tcd, and the giant Brazilian processors of >40 000 tcd, where ethanol is produced in addition to sugar.

Cane Weighing and Testing. Cane is weighed in the delivery vehicle (other than boats) on platform scales, with a second weighing of the empty vehicle. When payment is based on cane quality, samples are taken from the truck (grab sample or, better, core sampler) [222] for analysis or from a hatch opening across the mill after the knives; the most modern system (Florida) is to sample the first mill juice from cane, on an accurately timed basis, where the truck is labeled and the label is related by a timing system to the juice from that truck's cane.

20.5.1. Cleaning

Hawaiian factories, where cane arrives with roots, mud, and rocks, first dry-clean cane to remove loose debris; then the cane is washed extensively. Louisiana factories, and others in muddy areas, wash cane on the ascending cane conveyer or feeder table as it enters the mill. Magnets above the table remove metal trash. Sand must be removed especially carefully because it can lead to erosion of downstream equipment.

20.5.2. Juice Extraction

Cane is *prepared* for extraction through chopping with sets (usually two) of revolving knives, which slice it into small pieces (1–4 inch, ca. 2–10 cm, ideally) but do not extract juice. Cane passes from knives through a shredder, often a swing-hammer mill, which mashes up the sliced cane, breaking open cells to allow increased extraction at the next stage. Juice is then extracted by either milling or diffusion.

Milling. Shredded cane passes through a crusher mill and a series of three to seven subsequent sets of three-roll mills. The rolls are 2–3 m long. These mills are built in a multitude of structural variations. Four- or five-roll mills are becoming more common. A three-roll mill with pressure feeder combination is shown in Figure 13. Continuous-pressure feed improves the speed and efficiency of extractions. Water (10–35 % by weight of cane) is applied to the milling train in a reverse direction to the cane, on the last mill, with juice recycled backward, to increase extraction in a process called "imbibition." *Crusher juice* is obtained from the first mill; it is highest in sugar (12–17 %). *Last mill* or *residual juice* is that from the final mill (1–3 % sugar). Juices from all mills are strained or screened into tanks and called *mixed* or *dilute juice*.

Diffusion (see Section 7.4). The sugarcane diffusion process has been developed from sugar beet extraction. Here, cane from the shredder must be prepared further in a fiberizer, or extended shredder, for best extraction. Because of this finer preparation, diffusion gives a higher degree of extraction (93–98 %) than milling (85–95 %); therefore, further cane preparation is increasingly used in mill trains also. Finely prepared cane enters a multicell, countercurrent diffuser of linear (→ Liquid–Solid Extraction, Chap. 2.3.2), diagonal (→ Liquid–Solid Extraction), or circular design (→ Liquid–Solid Extraction, Chap. 3.1) [7, 15]. In the diffusers, shredded cane moves countercurrent to hot water (75 °C). This system is applied for *cane diffusion*. Various combinations of sets of mills with a diffuser are called *bagasse diffusers*. Bagasse emerging from the diffuser must be dewatered to reach the approximately 50 % moisture of mill-run bagasse; at this moisture, bagasse can be fed as fuel to factory boilers.

20.5.3. Factory Fuel

Cane factories, except for those in the People's Republic of China and Cuba (where wood fiber is in short supply and bagasse is a fiber source), burn their own bagasse and are more than self-sufficient in energy, with excess energy used for cogeneration [Cuba, United States (Hawaii, Florida), Mauritius], distillery operation (Brazil, other South and Central American countries, Southeast Asia), or increasingly, a refinery at the end of the mill (a white end refinery).

20.6. Cane Factory Process

The factory process, outlined in Figure 14, is general for the production of *raw sugar,* a light-brown product that will subsequently be refined into white and brown sugar food products (see Section 13.1). Cane sugar has traditionally been processed in two stages because sugarcane cannot be stored after harvest: a crude raw sugar product was made, seasonally, in cane-growing areas and shipped to areas of major consumption (North America, Japan, Northern Europe), where it was refined into final products. Raw sugar is traded on the commodity futures markets. A white sugar product (*mill white, plantation white crystal*) has traditionally been produced at sugar factories in the tropics for local household and industrial use; it is described in Section 20.7, and traditional refineries are described in Section 20.8.

Figure 14. Schematic of sugarcane factory process for raw sugar manufacture
a) Mill or diffuser; b) Clarification; c) Multistage evaporation; d) Vacuum crystallization

Juice treatment for raw sugar manufacture includes clarification, evaporation, and crystallization. The mixed juice extracted from cane is at pH 4–5, dark colored, and turbid. For *clarification*, the juice is heated to < 75 °C to destroy invertase and other enzymes, and treated with lime (milk of lime or lime in a sugar solution, named "lime saccharate") at concentrations of ca. 0.5 kg of CaO per tonne of cane to increase the pH and stop sucrose inversion. Many different modifications of the process exist, along with various designs of clarifiers and feeders; heating and liming are sometimes done in reverse order, depending on juice purity. Lime and flocculating polymer (→ Flocculants, Chap. 2.2, → Flocculants, Chap. 2.3, → Flocculants) settle out of heated juice in the clarifier tanks, taking suspended and colloidal solids (bagasse, soil, inorganic material, waxes, gums) with them in a process called *defecation*. Clear, clarified juice is pumped off the top of the clarifier tanks; muds are pumped from the bottom and filtered on rotary vacuum dry filters, on which residual sugar is washed out. The filtrate is returned to the mixed juice or mixed with clarified juice; the latter procedure is a source of contamination unless filtrate has been clarified with a flotation clarification step, e.g., talo filtration (see Section 20.8) [223, 224].

Clarified juice, which contains about 13–15 % solids, is pumped directly to a series of

multiple-effect *evaporators*, in which the vapor from the first effect is used to heat the second, and each subsequent effect (usually three to five) is operated at vacuum and lower temperature (see Section 9). Many designs and combinations of evaporators are in use [7, 15]. Scale buildup in evaporator bodies reduces heat transfer and must therefore be removed; for this "boilout," the factory stops processing several times per season, unless it has a second set of evaporators. *Evaporator syrup* (corresponding to thick juice in sugar beet processing) of 62–69 % solids content is the product. Syrup in some modern factories is clarified in an additional step by flotation clarification to produce high-grade raw sugar for sale or for the factory's own refinery [225].

Syrup is pumped to the *crystallization station*, a series of single-effect vacuum pans; again, many designs and combinations exist [7, 15] (see also Section 10.1). In a pan, syrup is evaporated to supersaturation and seeded with fine sugar crystals, which act as nuclei for crystal growth. When crystals have grown to desired size and number, the crystal–syrup mixture (massecuite, fillmass) is discharged (the action of emptying the pan is called a "strike") into a mixer, and from there to a centrifugal (basket-type, batch centrifugal for high-grade sugars, continuous for low-grade sugars), where the mother liquor syrup is spun off ("purging") and the crystals are "washed" (i.e., sprayed with a fine stream of water in the centrifugal to remove most of their syrup coating so that they may be free flowing in bulk storage) (see Section 11).

Runoff syrup from the crystallized evaporator syrup (A-strike) is called *A-molasses*; it is boiled again to crystallization in a vacuum pan (B-strike, with runoff *B-molasses*). This serial boiling is continued usually three times (see Section 13.1), with various modifications, cuts, and cross-blending, to obtain the maximum yield of sugar. Crystallization is the cheapest and most effective purification step; sugar syrups of purity lower than massecuite are cooled in open stirred *crystallizers* at atmospheric pressure until sufficient crystals have formed for centrifugal separation. Designs for crystallizers are as numerous as those for vacuum pans [7, 15]. The lowest grade of molasses from which no more sugar crystals can be recovered economically is *blackstrap molasses*, a heavy, viscous, bitter material containing 26–40 % sucrose, 9–23 % invert sugars, and at least 80 % total solids. About 24–40 kg of molasses is produced per tonne of cane, depending on the purity of the cane juice and the processing systems.

Sugar cane juices have a roughly ten times higher invert sugar content than beet juices but their amino acid content is 50 % lower than that of beet juices. Thus, color formation can be limited by working at low temperatures and low pH values during juice purification. The invert sugar is not destroyed during all processing steps.

The A- and B-strike sugars are usually mixed to become the raw sugar of commerce, traded on a 96°Z (pol) basis. Very high pol (VHP) sugars of more than 98°Z (pol), are produced in some areas (e.g., Hawaii and South Africa) [226] by remelting B-sugars and washing the A-product extensively, sometimes after syrup clarification.

Raw sugar is cooled and dried on belts conveying it to bulk storage (dryers are not common) and is weighed into the warehouse. The custom of bagging raw sugar for storage and shipping has almost ceased.

20.7. Direct White Sugar Factory (see Section 13.2)

The characteristic reagent in the processes for direct white (mill white, plantation white) sugar production is sulfur dioxide (produced by burning sulfur in air or from liquid SO_2), which is used to inhibit nonenzymatic browning by addition either directly into the juice or into the carbonated syrup to lower the pH during sulfitation. Direct white sugar is produced by a variety of processes:

1) Settling clarification and juice sulfitation [12, 15]
2) Single or double carbonation with syrup sulfitation [12, 15]
3) Blanco Directo process (juice sulfitation; juice filtrate and syrup clarification) [223, 224]

In all these processes, powdered carbon, in pressure filters, may be used for additional decolorization. Various modifications of processes 1 and 2, using carbonation methods similar to those for beet sugar production, are usually applied in India, China, Africa, Southeast Asia, and

South America for sugar for domestic production and are discussed thoroughly in older literature [12]. The above processes are supplanted in newer factories in these countries by type 3 Blanco Directo processes (see Fig. 15), which can readily convert a raw sugar factory to production of white sugar of quality higher than the standard mill white and suitable for food and beverage processors in the tropics. Many factories produce either direct white or raw sugar at different time periods [227].

20.8. Refining [228] (see also Section 13.4)

Traditional cane sugar refineries use raw cane sugar at 96 to 98°Z (pol) as input ("melt") and produce not only a range of granulated and liquid sucrose products, similar to those described in Chapters 14 and 15, but also a range of brown sugars and syrups, as well as edible syrups (molasses). The brown products have characteristic palatable cane and cane molasses flavors, not available from sugar beet. A generalized refining scheme is shown in Figure 16. Refineries are large processing plants operating around the clock typically for five (weekend shutdown) or ten days (four-day shutdown). Fuel for free-standing refineries is fuel oil, natural gas, or coal, according to local availability; a few refineries have extended their power plants to generate extra electricity for the local grid; refineries attached to raw sugar factories use the factory's excess bagasse fuel.

The quality of incoming raw sugar is paramount for efficient operation. Sucrose content (pol) is a universal quality criterion. Color, ash (inorganic), invert sugar, moisture, dextran content, and grain size are other criteria that may be included in raw sugar purchase contracts [229].

Raw sugar is weighed into the refinery from rail car, ship, or raw sugar warehouse, and conveyed to the affination station, where it is mingled with a heavy syrup (80 % solids content), then spun in basket centrifugals and washed with a spray of water to remove the added and the integral syrup coatings. The washed raw sugar is dissolved (melted) to give a washed sugar liquor of ca. 70 % solids content, which is pumped to clarification. Three types of clarification exist:

Phosphatation. Phosphate (phosphoric acid, P_2O_5, concentration up to 400 mg/kg solids) and calcium hydroxide (as milk of lime or sugar solution of lime, up to pH 7.5–8.3)

are combined with the sugar liquor in an aerated flotation clarifier (Williamson, Jacobs, or Sucrest designs). Calcium phosphate forms, occluding suspended solids and inorganics in its mass, and floats to the surface where it is scraped off by rotating blades. Clarified liquor (syrups are called liquors in refineries) is pumped out from the bottom of the clarifier [7, 14, 15, 223]. The process removes 25–40 % color, ash, and turbidity from the sugar liquor.

Talo Phosphatation. Phosphatation is performed as described above with the addition of *color-precipitating chemicals* (quaternary ammonium compounds with long-chain fatty acid substituents) and a series of mud-desweetening steps, which remove a greater amount of color (30–50 %), ash, and turbidity [223 – 225, 227]. This process is widely used in white end refineries and has almost replaced traditional phosphatation.

Carbonation (Carbonatation in the United States and the United Kingdom). In this process, lime and carbon dioxide are mixed in liquor in a two-stage process similar to that for beet sugar processing but carried out on liquor of 65–70 % solids.

Any type of clarification is followed by *filtration* through leaf-type vertical or horizontal pressure filters. Carbonated liquors, containing calcium carbonate, may require addition of diatomaceous earth as a filter precoat. Phosphatated liquors are generally filtered with the addition of diatomaceous earth as precoat and body feed.

Filtration, often a refinery bottleneck, especially with poor-quality raw sugar, is followed by *decolorization* with bone char (traditional), granular activated carbon (now most common), or ion-exchange resins, or any combination of these (see Sections 13.4, 14.4). Discussions on comparative merits and regeneration of these decolorizing systems may be found in [7, 15, 230, 231].

Decolorized liquor, or fine liquor of very pale yellow color, is evaporated further to 72–74 % solids and sent to *crystallization* in a series of vacuum pans, as with raw cane sugar and beet sugar. Refinery strikes are designated 1, 2, 3, etc. Four to six white sugar strikes are common. The lowest-grade runoff syrups are sent to a second series of pans and crystallized to improve sugar recovery. *Brown low-grade runoff syrups* and refiners' final molasses are sold for food processing, brewing, and blending to make cane syrups and edible molasses.

Refined brown sugars ("soft sugars" in the trade, see Section 15.7) are made by crystallizing sugar from a mixture of third and fourth runoff syrups and affination syrup (boiled brown sugars) or by coating white sugar crystals with a brown-liquor–caramel-syrup (painted or coated brown sugar). Table 14 shows the composition of typical raw cane sugar and of refined granulated, direct mill white, and Blanco Directo sugar.

White end refineries are referred to above. These have the advantage of using available fuel from the raw sugar factory to which they are attached, although this may require seasonal operation. Increasingly, raw sugar factories are grouping together and building a white end refinery to process their raw product [224]. Processes employed are typically melting without affination because the raw sugar can be washed well in the factory; use of color precipitants (talo phosphatation); decolorization with granular activated carbon or ion-exchange resin; and crystallization. Customarily, only white sugar is made, and low-grade syrups are returned to the attached raw sugar factory. This system seems to be the trend for the future, replacing the large free-standing refinery.

21. Sugar from Other Plants

Palm Sugar. The production of palm sugar is of some importance in India (production 170 000 t/a), Burma (production 20 000 t/a), Indonesia, and in the Philippines. Of the nine species of palm with sucrose-containing cell sap, four are cultivated in India: *Phoenix sylvestris*, *Borassus flabilliformis* (palmyra), *Cocos nucifera* (coconut), and *Caryota urens* (sago). The tapping of palm juice (neera) is accompanied by many difficulties.

After purification with lime and skimming of the floating precipitate, the palm juice is concentrated to a thick syrup by evaporation in open pans [232]. It is vigorously stirred as the sucrose begins to crystallize. This "massecuite" is then filled into clay molds or palm-leaf baskets

Table 14. Composition of typical raw, refined granulated, direct mill white, and Blanco Directo sugars [212, 219]

Compound	Raw sugar	Refined sugar (from raw sugar)	Mill white	Blanco Directo
Sucrose, °Z	97.73	99.9	99.6	99.9

* ICUMSA unit.

through which the mother syrup can drain off. For the production of 1 t of palm sugar, ca. 2.3 t of palm syrup with a solids content of 60 % and a purity of 84 % are required [24].

Maple Sugar and Maple Syrup [23]. In the United States (especially the state of Vermont) and Canada, maple syrup and maple sugar are isolated from the juice of the sugar maple (*Acer saccharinum*). Maple syrup and maple sugar are used in the production of food syrup, preserved food, jams, and ice cream and in the fermentation of tobacco because of their special flavor. Annual production in the United States is ca. 9000–10 000 t of maple syrup and 130–150 t of maple sugar. Juice is tapped from maple trees from February to April. The tree must be about 40 years old before juice can be obtained. It then produces juice containing 2.5–3.5 % sucrose for 100 years. The juice is tapped from a hole bored in the trunk about 1 m from the ground. Before evaporation, maple juice is purified by adding milk of lime, and the precipitate is filtered off. About 0.9–1 kg of maple syrup with a solids content of 66.8 % (66.1 % carbohydrates and 0.7 % ash) is obtained per tree per year [233].

Sugar from Sweet Sorghum. Like sugarcane, sorghum (*Andropogon sorghum saccharatum*) [22] belongs to the class of grasses. It is grown in the southern parts of the United States for production of a sweet syrup and was studied as a sugar and energy crop in, e.g., Brazil, Hungary, Austria, Italy, Germany, Belgium, Greece, and Spain. As with sugarcane, the cell juice, which contains ca. 10–14 % total sugars (glucose, fructose, and sucrose), is obtained by pressing. Subsequent process steps are also similar to those used in the cane sugar industry. In Louisiana, extensive cultivation was attempted to prolong the total working time of a factory by introducing a sorghum campaign.

Date Sugar Syrup. Ripe dates contain about 30 % water. The largest part of the solids is water soluble and consists mainly of glucose, fructose, and small amounts of sucrose. The seed is a problem in processing dates to liquid sugar. Nevertheless, techniques [20] for the isolation of invert sugar from dates have been worked out and are used on a large scale in Iraq.

Sugar from Sweet Corn (*Zea Mays L.*). The isolation of sugar from the sucrose-containing cell juice of corn stalks has achieved no technical importance [21].

22. Quality Demands on Sugar and Side Products of Sugar Production

22.1. Refined and White Sugar

In the past, white sugar was divided into "refined sugar" and "white sugar." "Refined sugar" referred to a sugar obtained by recrystallization of crystalline sugar.

Today, white sugar is evaluated and labeled only according to its chemical and microbiological quality. Since white sugar is a commercial product worldwide, specifications for it exist in the form of official, internationally and nationally obligatory regulations or standards in pharmacopeias, and voluntary quality agreements between sugar manufacturers and the sugar processing branches of industry.

The sucrose content of white sugar is almost always > 99.7 %. For this reason, evaluation is based not only on the content of water, invert sugar, SO_2, heavy metals, etc., but also on the

cumulative parameters for the individual classes of impurities, such as:

1) Ash content (i.e., content of inorganic or organic salts)
2) Color in solution (i.e., content of Maillard products and colored higher molecular mass compounds)
3) Color type (i.e., optical appearance of the sugar by visual comparison with a type series)

The Codex Alimentarius [234] divides white sugar into two categories, A and B, and stipulates certain requirements for them (Table 15). Specifications valid within the EC [187], which have been accepted by many other countries, are generally used in international white sugar trading (Table 16). The requirements to be met in the United States are published in the Food Chemical Codex [188].

Table 15. Essential composition and quality factors for white sugar, according to WHO–FAO [234]

Specification	A	B
Sucrose content, °Z	>99.7	>99.5
Invert sugar content, %	<0.04	<0.1
Conductivity ash, %	<0.04	<0.1
Loss on drying (3 h at 105 °C), %	<0.1	<0.1
Color, IU *	<60	<150
Food additives, mg/kg		
Sulfur dioxide	<20	<70
Contaminants, mg/kg		
Arsenic	<1	<1
Copper	<2	<2
Lead	<0.5	<0.5

* ICUMSA units.

Identification: Dissolve 26 g of the sample in water and dilute to 100 mL at 20 °C. Determine the polarization in a saccharimeter, by using a 20- cm tube.

Further quality requirements for white sugar are as follows:

Sucrose content, °Z	99.8–100.2
Arsenic (as As), mg/kg	< 1
Color, ICUMSA units	< 75
Conductivity expressed as residue on ignition, %	< 0.15
Heavy metals (as Pb), mg/kg	< 5
Invert sugar, %	< 0.1
Lead, mg/kg	< 0.1
Loss on drying, %	< 0.1
Ash residue %	< 0.15
Specific rotation $\left([\alpha]_D^{20}\right)$	+ 65.9–66.7°

The heavy-metal contamination of white sugar is very low (Pb < 0.1 mg/kg; Cd < 0.002 mg/kg; Hg < 0.003 mg/kg within the limits of detection). The same applies to the concentration of herbicides, fungicides, and insecticides, which lie within the analytical limit of detection.

Apart from these official minimum requirements, other parameters are important for storage and industrial processing [235]. These include the total (< 0.06 %) and surface water (< 0.03 %) content [197]; the content of water-insoluble solids [236], which must be < 7 mg/kg (determined with an 8-µm filter) for some consumers; and the filth [237] (insect parts and rodent hairs). Furthermore, for the beverage industry, the saponin content (< 1 mg/kg) of white beet sugar and the polysaccharide content (dextran < 100 mg/kg) of white cane sugar are important because both cause foam and floc formation [238]. The content of betaine, amino acids, and cations (calcium) can also be of significance in individual cases [239].

For storage in small silos (up to 100 t), the emptying and internal factory transport of sugar to the places of use, dust content (< 200 µm), and grain-size distribution are of substantial importance. Sugar with a d' of 1.0–1.2 mm, $n >$ 3, and a dust content of < 1.5 % is most suitable for this purpose.

The screen analysis of sugar is evaluated according to the RRSB (→ Size Enlargement, Chap. 3.3) or to the Gaussian distribution (→ Size Enlargement, Chap. 3.3).

Although sugar is a food with one of the lowest germ contents, certain consumers (manufacturers of nonalcoholic drinks, canned food industry, etc.) demand practically germ-free sugar (total content of microorganisms < 200 per 10 g, yeast, mold < 10 colonies per 10 g etc.). Target values for the permitted microorganism burden of sugar, especially for "liquid sugar," have been put forward by the National Soft Drink Association, United States (Bottlers Test), and the National Canners Association, United States [240] (Canner's Test), and are maintained by the sugar industry on a voluntary basis. The internationally recommended microbiological methods of analysis are found in ICUMSA proceedings or in the ICUMSA Methods Book [55].

Table 16. Quality criteria for white sugar according to EC sugar market regulations (EC 1972) (grade 2 is white sugar of standard quality), according to [187]

Quality criterion	Grade*		
	1	2	3
Sucrose content (polarization), °Z (min.)		99.7	99.7
Moisture content, % (max.)	0.06	0.06	0.06
Invert sugar content, % (max.)	0.04	0.04	0.04
Color type, Brunswick unit (max.)	(2)	(4.5)	(6)
Points (0.5 unit = 1 point)	4	9	12
Conductivity ash, % (max.)	(0.0108)	(0.0270)	
Points (0.0018 % = 1 point)	6	15	
Color of solution, IU (max.)	(22.5)	(45)	
Points (7.5 units = 1 point)	3	6	
Points according to EC point system (max.)	8	22	

* Quality criteria for all grades: sound, fair and marketable quality, dry, in homogeneous granulated crystals, free-flowing.

22.2. Molasses

If molasses is used in feed, it must comply with feed regulations of individual countries with respect to composition, heavy-metal content [241], agricultural pesticide residues [242], and labeling as single or mixed feed. The same applies to other feed obtained in the production of sugar, such as pressed pulp, dried pulp, molassed dried pulp, residual molasses, etc.

If molasses is sold as a raw material (nutrient medium) for the production of ethanol, yeast, citric acid, or lactic acid, and for other chemical or biochemical processes, general trading conditions or as-agreed specifications are valid [solids content (min.) 76.3 % = 40.5°Bé].

Beet Molasses. Beet molasses accumulates in production with a solids content of 80–89 %. Apart from sucrose, the solids in molasses comprise, depending on purity, 40–50 % of nonsugar substances, which can be divided as follows [243] (all nonsugars = 100 %):

1) Other usable saccharides such as glucose, fructose, raffinose, kestoses, and galactinol (1.5–4 %)
2) Inorganic nonsugar substances: K^+, Na^+, Mg^{2+}, Ca^{2+}, Fe^{3+}, Pb^{2+}, Cl^-, SO_4^{2-}, NO_3^-, NO_2^- (ca. 33 %)
3) Nitrogen-containing organic nonsugar substances [244]: pyrrolidonecarboxylic acid, γ-aminobutyric acid, glutamic acid, aspartic acid, glycine, tyrosine, serine, alanine, leucine, isoleucine, valine, betaine, peptides, and Maillard products (42 %)
4) Nonsugar substances containing no nitrogen: citric, malic, fumaric, succinic, oxalacetic, oxalic, tartaric, glycolic, lactic, arabonic, saccharinic, formic, acetic, propionic, butyric, and glacturonic acids; araban and galactan fragments

Apart from these constituents, other compounds have been detected in the part-per-million range in beet molasses [245]. Investigations have been carried out in past years because molasses-containing substrates have occasionally suffered from inhibition of growth or metabolism, which was assumed to be caused by pesticide residues. The investigations could not verify these assumptions [246]. However, increased concentrations of volatile carboxylic acids (formic and propionic acids) and furfural-like compounds, which can arise on heat treatment of molasses in the acidic range, appear to exert inhibitory effects under certain conditions.

Cane Molasses (Blackstrap). Cane molasses has a different composition from beet molasses because the components of sugarcane cell juice are different. According to [247], normal cane molasses with a water content of 17–25 % has a total sugar content (sucrose, glucose, fructose) of 45–50 %. The content of polysaccharides (dextrans, pentosans, polyuronic acids) is 2–5 %, and that of peptides and free amino acids is 2.5–4.5 %. The content of nitrogen-free acids (aconitic, citric, malic, oxalic, mesaconic, succinic, fumaric, and tartaric acids) is 1.5–6 %. The content of cations, determined as carbonate ash, varies between 7 and 15 %.

The carbonate ash has the following composition: 30–50 % K_2O, 7–15 % CaO, 2–14 % MgO, 0.3–9 % Na_2O, 0.4–2.7 % Fe_2O_3, 1–7 % SiO_2 and insoluble substances, 7–27 % SO_4^{2-}, 12–20 % Cl^-, and 0.5–2.5 % P_2O_5.

The storage of cane molasses is problematic because of its low pH. Chemical or microbiological decomposition of cane molasses stored in tanks occurs from time to time [248].

Cane molasses can be utilized in part like beet molasses (see above), e.g., as pelletizing aids. It behaves differently as a fermentation substrate; because of its aromatic taste and odor, it gives rise to arrack and rum on alcoholic fermentation. Aconitic and itaconic acids are obtained from cane molasses [249].

Three types of cane molasses are available commercially, corresponding to the water and sugar (sucrose, glucose, and fructose) content: *superior blackstrap molasses* (water content = 23.4 %, total sugar content = 53.5 %), *blackstrap molasses* (water content = 23.5–26.4 %, total sugar content = 48.5–53.4 %), and *utility blackstrap* (water content = 26.5 %, total sugar content = 42.5–48.4 %).

High-Test Molasses. High-test molasses is not molasses in the original sense of the word, which defines it as the final syrup obtained after crystallization of sugar. It is rather a thin juice that is two-thirds inverted, only moderately purified, and concentrated to about 85 % solids. High-test molasses consists of about 15.5 % water, 27.0 % sucrose, 50.0 % invert sugar, and 2.25 % ash.

Dry Molasses. As a result of its high viscosity, molasses is difficult to handle and, consequently, cannot be used alone as feed in agriculture. To open up this market, methods have been developed for the production of both beet and cane dry molasses. The drying operation used is either spray drying [250] or drum drying [251]. To make drying possible, carriers (e.g., calcium oxide [250, 251]) or floury feeds [252] (e.g., alfalfa flour or whey powder) must be added to the molasses.

22.3. Vinasse

After the fermentable sugar in molasses has been biotechnologically used and the compounds produced have been isolated, the nonsugar substances that are not assimilated and metabolic side products remain more or less completely in the nutrient medium. In Baker's yeast fermentation, for example, ca. 35–45 % of the total nitrogen content of the beet molasses is assimilated. These substrates are being increasingly subjected to multiple-effect evaporation to give a solids content of 70 %. They are referred to as vinasse or condensed molasses solubles [249]. Vinasses have gained approval by feed regulating authorities, and are used as feed or soil conditioner [253]. Efforts are also being made to use vinasse directly for the production of biogas [249].

22.4. Liquid Feed Supplement [254]

For large animal farms (cattle, sheep), a liquid feed based on diluted molasses (60–70 %) is produced in the United States. Urea, biuret, mineral substances, trace elements, vitamins, etc., are added to optimize requirements in the basic feed and are then added to this liquid feed.

22.5. Beet Pulp

Beet pulp obtained on extraction of cossettes is pressed to an appropriate solids content, dependent on individual factory conditions. If pressed pulp is delivered directly as feed or for preservation by ensiling, it is mostly pressed to 18–22 % solids content. If pulp is dried after pressing, factories try to achieve the highest possible solids content by pressing, mostly in the range of 28–35 %, to save drying costs. Their solids, beet marc, consist of ca. 20–25 % cellulose, 20–25 % pectin, 18–23 % araban, 5–10 % galactan, 6–10 % raw protein, 5–6 % ash, and 4–5 % sugar.

In contrast to other agricultural animal feeds, pressed pulp is normally ensiled hot, at 50 °C, with the aid of thermophilic lactic acid bacteria [255]. Shrink-wrapped round bale ensiling, a well-known development in agricultural ensiling, was studied as a new way of marketing pressed pulp [256].

Dried pulp is obtained by drying pressed pulp (see Section 17.2) to a solids content of 90–92 %. If 1–3 % of molasses (based on the weight of the pressed pulp) is added to the pressed pulp before drying, *molassed dried pulp* with varying sugar content (9–30 %) is obtained. Apart

from sugar content, the concentrations of HCl-insoluble substances, calcium, and ash are controlled in individual countries according to feed regulations.

Sepa patent cossettes are obtained by drying on pressed pulp a previously homogenized molasses preliming flocculation mixture(see Section 8.1). They have a solids content of 91–92 % and consist of ca. 9.9 % raw protein, 12.7 % raw fiber, and 9.8 % raw ash of which 6.1 % is $CaCO_3$ and 0.65 % is P_2O_5. The sugar content is 17–18 %. In the case of *Torno slices*, carbonation sludge (see page 26) is dried to 3 % solids instead of the preliming precipitate.

"Steffen cossettes" are obtained by drying partially desugarized wet pulp (sugar content 28–35 %). Dried pulp with a total nitrogen content of 2.5–3.5 % is obtained directly by extraction of cossettes with liquid ammonia (see Section 7.3) or by treatment of dried pulp with liquid ammonia in pressure vessels [257]. Feed with a high NPN (nonprotein nitrogen) total nitrogen content can also be produced by addition of urea to a dried pulp–molasses mixture. The finished feed consists of ca. 60 parts of dried pulp, 25 parts of molasses, and 15 parts of urea. Another production process for amide cossettes starts directly with pressed pulp [258]. To obtain a feed with a higher NPN-level also an aqueous $(NH_4)_2SO_4$ solution (1 % based on dry substance) can be mixed with pressed pulp.

Full-quality beet cossettes are obtained by drying fresh beet slices (see Section 6.9) to a solids content of 92–94 %. Their composition corresponds to that of fresh beet.

23. Economic Aspects

The worldwide sugar economy is determined by the following factors:

1) Sugar is an agricultural product, affected by crop failure and record crops (i.e., it is available in changing supply)
2) The demand for sugar depends on eating habits, the economic situation, and population development
3) Since the 1970s, apart from traditional glucose syrups, sugar has had a serious competitor in the form of HFCS (→ Glucose and Glucose-Containing Syrups)

Today, sugar is a staple food. In industrialized countries, 10–15 % of the daily intake of calories is provided by sugar and sweeteners produced from corn or wheat. In some countries the sugar consumption per person per year has remained practically unchanged for decades. For instance, it remained virtually constant in the United States and the United Kingdom from 1920 into the 1980s.

Until 1850, the cane sugar industry alone dominated the market. About 5000 t/a was imported into Europe of which, on average, 10 kg per person per year was consumed in England, 7 in the Netherlands, 2 in France and the German "Zollverein," 1 in Austria and Italy, and 0.5 in Russia [259].

The beet sugar industry then developed in Central Europe and became a competitor of the cane sugar industry. In an effort to be independent of imports, more and more countries started their own sugar production and switched from being importing to possible exporting countries. Nowadays, more than 100 countries have their own sugar production from sugarcane or sugar beet.

Countries that have a permanent sugar requirement do not buy sugar on the open market, but often conclude long-term supply contracts with exporting countries at preferential prices. For instance, the United States awarded export quotas to individual countries, especially Cuba until 1960. Thus, the United States was the main purchaser of Cuban sugar until that time. Since Fidel Castro's revolution and until 1990, the Eastern-bloc countries, the Soviet Union, and the People's Republic of China have received most of the Cuban sugar. Sugar imports into the United Kingdom were also controlled by special regulations (Commonwealth Sugar Agreement of 1951) or arranged in agreements such as the African, Malagasy, or the Lomé Agreement (1971). In the latter, the countries of the EC were committed to buy 1.3×10^6 t of sugar per year from these countries at EC prices. For this reason, only a fraction, about 10–15 %, of world sugar production is traded on the stock markets of New York, London, and Paris.

Since at all times and in all countries, sugar has represented a source of taxes that are profitable and easy to raise, good statistics are available. Table 17 shows the development of world sugar production and cane sugar production as

percentage of total production since 1900 [260]. Worldwide sugar production has increased tenfold since 1900. At more than 50 %, the percentage of beet sugar was at its maximum before World War I. Since 1940, it has been in the range of 34 % (1980–1992) to 40 % (1960).

The reason for the favorable development of beet sugar production in 1964–1965 was widespread sugar beet cultivation in the Soviet Union after World War II. Since 1970, the percentage of cane sugar production has increased to about 75 % and has remained at that level.

Since July 1, 1968, EC members have formed a common sugar market based on decree No. 1009/67 EEC from December 18, 1967, which was valid largely unchanged until July 2006. For the main areas of surplus production in the EC, a target price and an intervention price were set for unpacked white sugar of a definite standard quality ex factory (see Table 16, grade no. 2). Raising a surcharge for imports from third countries and payment of a reimbursement on exports should compensate for price differences within and outside the EC. A desirable limitation of sugar production was achieved by establishing basic quotas with a price and sales guarantee by the EC for each sugar-producing company (A quota: the level depends on domestic requirements in the EC). These guarantees were reduced (B quota) for the amount that exceeded the basic quantity (ca. 20–30 % of the A quota). If the EC suffered financial losses due to exporting part of the quota, this was reapportioned among beet growers and sugar factories (production tax). If the sugar production of a company exceeded the entire quota amount, this sugar (C sugar) had to be sold within a year outside the EC and was the sole responsibility of the company.

Since the 1980s, development of the world sugar market has led to tougher competition among previously nationally oriented sugar industries. Antiquated factories have been shut down or modernized with high investments. As a result of transport costs, factories are now located in cultivation areas. For the same reasons, the size of factories is kept within limits.

In 2006, this tougher competition led to a reform of the EU sugar regime, which was published as decree No. 318/2006 EC of February 20, 2006 and which came into force on July 1, 2006, when the former EU directive expired. This reform was necessary especially after a complaint by Australia, Brazil, and Thailand about increased EU sugar exports with the aid of subsidies. This complaint was confirmed by a WTO panel in 2004 and again in 2005. With the new regime, the intervention system was replaced by a white sugar reference price, which is to fall by 36 % until 2009 according to decree No. 318/2006 EC. A number of ACP (African, Carribean, Pacific) and LDC (least developed countries) states as well as European countries will be unable to produce sugar at this low price. Thus, a restructuring fund was installed to encourage uncompetitive sugar producers to leave the industry, in order to reduce the pressure on the EU domestic market. For sugar beet farmers a minimum price, to fall by 20 % after three years, and a monetary compensation were fixed. A and B quotas were combined and new quotas were fixed, based on 2005/06 data [261]. The new regime will ensure a sustainable future for the remaining EU sugar production, but will cause large changes for individual countries.

Regulations for the production of sugar (prices, quotas) similar to those of the EC also exist in other countries, such as the United States, India, and Brazil.

Consumption per person in a series of countries is listed in Table 18 [262].

The world market price of sugar undergoes large fluctuations, as shown in Table 17 and Figure 17.

Figure 17. World market and prices for white sugar, monthly values Paris 1988–1993 [263]

To stabilize production and prices, the sugar industries of Cuba, Japan, Poland, Hungary, Bel-

Table 17. Development of worldwide sugar production [260]

	Raw sugar, 10^6 t	Cane sugar, %	Average annual quotation of the New York stock exchange, cents/lb

gium, Germany, and Czechoslovakia signed an agreement on May 9, 1931, in Brussels (Chadbourne agreement), which stipulated a limitation of sugar production in subsequent years. The supply (production and sales of surplus) should not exceed the demand. The international sugar agreements of 1937, 1953, 1958, and 1968 had the same goal.

To increase the export proceeds of developing countries and stabilize international trade, a new international sugar agreement came into effect in 1977, which was signed by 40 sugar exporting countries and 15 sugar importing countries and was the last one containing direct market intervention instruments or so-called economic clauses [260]. This agreement was ratified by the United States in 1980 and the EC participated with constructive proposals, but was never a member of the agreement. The aims of the agreement should be achieved by export quotas in combination with reserves, which should be used in the case of increasing demand and refilled in the case of falling prices. A minimum price for raw sugar of 13 cents per pound and a maximum price of 23 cents per pound were agreed upon. The world market price was in this desired range for only a relatively short time. An agreement on the financing of reserve storehouses could not be reached. Consequently, the intended stabilization of world market prices was not achieved.

This agreement was replaced by a so called administrative agreement, ratified in 1984, 1987, and–after withdrawal of the United States–by a service agreement, signed in 1993, 1995, 1997, 1999, etc., with a possibility of indefinite extensions, each valid for two years. The aims now are merely to intensify international cooperation in sugar production and sales, to serve as a forum for international consultations on sugar and on the possibilities of promoting the world sugar economy, to facilitate trade by recording and making available information on the world market for sugar and other sweeteners, and to promote the demand for sugar for new purposes.

In the past, beet and cane sugar and, to a small extent, starch hydrolysates (glucose syrup, glucose) competed with each other on the market for nutritive sweeteners. Starch hydrolysates are used for technological reasons in the industrial production of certain foods. Since 1975, HFCS (isoglucoses, → Glucose and Glucose-Containing Syrups) has appeared on the market as a direct competitor of "liquid sugar" in the United States, Canada, Japan, and some European countries. In 1991, the production of HFCS amounted to 7.8×10^6 t (solids), ca. 7 % of the world sugar market. These amounts substantially influence the sugar market worldwide.

Apart from the market for nutritive sweeteners, a market has developed for calorie-free (intense) sweeteners (→ Sweeteners), calorie-reduced (polyols, inulin hydrolysates, synthetic

polydextroses) sweeteners, and sweeteners with a definite nutritional physiological purpose [e.g., suitable for diabetics, noncariogenic sweeteners (fructose, → Fructose; polyols, → Sugar Alcohols)]. The percentages of individual product groups fluctuate greatly from country to country: for example, for intense sweeteners, ca. 10 % of the entire sweetener market is in the United States, 5 % in Germany, and < 0.5 % in developing countries [263].

1. Polyols, General

Historical Aspects, Nutrition Physiology. In the 1920s, the production and marketing of sugar alcohols (polyols) were begun to provide people who should not eat sugar (because they suffer from diseases, e.g., diabetics) with sweet foods such as confectionery, jams, hard boiled candies, and chocolates. Numerous studies have shown that the "sweet" taste is so important that no one wants to do without sweet-tasting products [7].

In the production of these foods, polyols function as a bulking agent (→ Sugar, Chap. 1.). The sweetness of the products is regulated by the addition of intense sweeteners (→ Sweeteners) [8].

Since the metabolism of polyols in humans is largely independent of insulin, polyols can be used in the production of foods for diabetics [9].

Furthermore, polyols have been found to be largely noncariogenic because they are not a substrate for plaque and acid formation in the oral

10.1002/14356007.a25_413

cavity. In fact, they stimulate salivation when consumed and, consequently, promote the remineralization of enamel. For this reason, polyols are suitable for the production of noncariogenic products, especially for consumption between meals (e.g., hard boiled candies, chocolates, biscuits). These products may be labeled "does not promote tooth decay" if they fulfill the following criterion: on consumption under stipulated experimental conditions, the pH of the plaque should not fall below 5.7 for a period of 30 min [10]. For pure polyols, the noncariogenicity (nonacidogenicity) decreases as follows: xylitol $\leq$ isomalt $<$ sorbitol, maltitol $<$ mannitol $\approx$ lactitol.

A third property that substantially differentiates polyols from sugar and corn syrups is their reduced physiological calorific value [11]. In the United States, the calorific value of mannitol is 2 kcal/g (ca. 8.3 kJ/g) [12]. In the EC, a physiological calorific value of 10 kJ/g is set for approved polyols: mannitol, sorbitol, xylitol, isomalt, lactitol, and maltitol [13]. An expert commission appointed by the Dutch government [14] and in 1994 an expert panel of the Life Science Research Office (LSRO) and the Federation of the American Societies for Experimental Biology (FASEB) [15] have evaluated the literature on this subject. The results are summarized in Table 1:

Table 1. Physiological calorific value of some polyols (in kJ/g)

Sugar alcohol	Nutrition Council 1987	LSRO Expert Panel 1994
Xylitol	15.0	~ 10.0
Sorbitol	12.0	7.5 – 13.8
Mannitol	8.5	6.7
Isomalt (Palatinit)	10.0	8.4
Lactitol	8.5	6.7 – 9.2
Maltitol	12.1	11.7 – 13.4
Maltitol syrup (see Sect. 7.1)		11.7 – 13.4

The exact value for the physiological energy yield of polyols is disputed scientifically, especially the question of whether dose or adaptation dependence exists [11], [16].

The reduced calorific value is due to the fact, that polyols are only partially absorbed in the upper intestine. Thus, a large part of the ingested polyols reaches the large intestine where it is degraded by bacteria to lower fatty acids, methane, CO_2, etc. Fatty acids are partially absorbed from the large intestine and, thus, enter intermediary metabolism.

Monosaccharide and disaccharide alcohols are absorbed and metabolized differently. The monosaccharide alcohols (e.g., sorbitol, xylitol, mannitol, erythritol) are directly absorbed from the small intestine, whereas the disaccharide alcohols must be cleaved first by intestinal carbohydrases into their constituents (i.e., monosaccharides and hexitols/polyols). For this reason, the disaccharide alcohols isomalt, lactitol, and maltitol are also called second-generation sugar alcohols. The rate of cleavage of individual disaccharide alcohols by the digestive enzyme systems of the human mucosa varies [17].

On the other hand, incomplete absorption is the reason for gastrointestinal side effects (e.g., gas, flatulence, diarrhea) that may occur if polyols are ingested in single doses of more than 20 g. The tolerance of polyols depends on the form of administration, i.e., whether the sugar alcohols are consumed as aqueous solutions in form of beverages or as components of solid foods such as chocolates [18], confectionery, or hard boiled candies. In solid foods, daily doses up to 60 g are well tolerated. The tolerance of polyols is not related to body weight: If equal amounts are consumed by children and adults, children do not exhibit greater sensitivity [19]. According to the Scientific Committee for Food of the EC [20], "a laxative effect can be observed when polyols are ingested in larger amounts. An intake of 20 g/person/day probably causes no undesirable laxative problems."

Especially in sweetmeats, confectionery, chocolates, and dietary products for diabetics, sugar alcohols are food ingredients and are not considered additives in the usual sense. In these products they can account for up to 5 % of the daily food intake. Consequently, the determination of an acceptable daily intake (ADI) value in the conventional sense by using the safety factor 100 after the determination of the "no-effect level", is not practicable.

Therefore, after reviewing long-term toxicological, carcinogenic, teratogenic, and reproductive studies, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) stipulated a "not-specified" ADI for the sugar alcohols xylitol, sorbitol, mannitol, isomalt, lactitol, maltitol, and for hydrogenated glucose-containing syrups [21]. The specifications and methods of analy-

sis adopted by the WHO/FAO are presented in [22] on the following pages: pp. 111 – 113 for isomalt, pp. 117 – 121 for lactitol, pp. 125 – 128 for maltitol, pp. 129 – 130 for maltitol syrups, pp. 134 – 139 for mannitol, pp. 241 – 244 for sorbitol, pp. 245 – 248 for sorbitol syrups, and pp. 267 – 271 for xylitol.

For the EC the specifications are summarized in a draft of a directive from June 1994 (EC 5757/III/93 EN-Rev.). The classification of the individual polyols varies from country to country according to their different food laws. They are sometimes regarded as food additives (e.g., within the EC [23]) and other times as food or generally recognized as safe (GRAS) substances, for example in the United States [24].

General Properties. Some of the sensory, chemical and physical properties of polyols are very different from those of sugar.

The *relative sweetness* varies from 1 for xylitol to ca. 0.4 for lactitol and mannitol. The relative sweetness of polyols is more concentration dependent than in the case of other carbohydrate sweeteners. The taste profile "sweet" is for some polyols very different from that of sugar, mainly because the enthalpy of solution of polyols differs from that of sugar (Table 2) [25–28]. Polyols with a higher positive enthalpy of solution cause a sensation of cooling (refreshment) in the oral cavity.

The *melting* (*sintering*) *points* of polyols range from 165 °C for mannitol to 92 °C for xylitol and sorbitol. When compressed to tablets, polyols with a lower melting point give products with a smooth surface. They can be ground to microcrystalline grains only with difficulty (required d' ca. 60 µm, n ca. 2; where d' is the diameter of the crystals and n a parameter of the Rosin – Rammler – Sperling distribution; → Sugar, Chap. 10.2.), as required, for example, in the production of chocolates and chewing gum.

Individual polyols differ greatly in their *hygroscopicity*. For instance, sorbitol (crystalline and aqueous solutions) and maltitol syrups are very hygroscopic, while mannitol and isomalt are practically nonhygroscopic with water activities (a_w values, → Foods, 2. Food Technology, Chap. 1.4.) lower than that of sugar.

The *solubility of polyols in water* as a function of temperature is shown in Figure 1. The solubility of the polyols sorbitol, xylitol, and maltitol at 20 °C is the same order of magnitude as that of sucrose. However, the solubility of isomalt and mannitol is significantly lower. For all polyols, the temperature dependence of solubility is greater than that of sucrose. The most important physical and chemical parameters, such as density, boiling-point elevation, and viscosities of aqueous solutions and melts, are listed in [29].

Figure 1. Solubility of polyols in water
a) Mannitol; b) Isomalt; c) Lactitol; d) Sucrose; e) Maltitol; f) Xylitol; g) Sorbitol

Chemically, sugar alcohols differ considerably from carbohydrate sweeteners because they lack a carbonyl group. Thus, Maillard reactions and the Strecker degradation are inhibited (little browning or flavor formation). In addition, mono- and disaccharide alcohols are much more resistant to enzyme systems, acids, alkalis, and the action of heat than sugar or glucose syrups.

Because of their noncariogenic properties and their reduced calorific value compared to carbohydrate sweeteners, sugar alcohols are suitable for the production of noncariogenic and reduced- calorie (light) products and products with a defined nutritional purpose (e.g., diabetics).

Table 2. Enthalpy of solution of saccharides and sugar alcohols

Compound	Enthalpy		
	kJ/mol	kJ/kg	Reference
Sucrose	6.21	18.2	[24]
Maltitol	6.7	23.0	[27]
Isomalt (Palatinit)	14.6	39.4	
Lactitol monohydrate	19.2	53.2	[26]
Sorbitol	20.2	111.0	[25]
Isomaltulose	21.66	60.2	
Mannitol	22.0	120.9	[25]
Xylitol	23.27	153.1	[24]

The sensory and food manufacturing properties of individual sugar alcohols vary substantially. Thus, proper selection of raw materials or the combination of several sugar alcohols enables sugar and glucose syrup to be replaced as bulking agents and sweeteners in all food categories in such a manner that the resulting products are acceptable to consumers.

2. Xylitol

Xylitol [*87-99-0*], $C_5H_{12}O_5$, M_r 152.15, is a naturally occurring, five-carbon sugar alcohol (pentitol) with a sweetness similar to sucrose. Xylitol is produced commercially by catalytic hydrogenation of D-xylose. It is used as a sugar substitute mainly in noncariogenic confectionery and special foods for diabetics, and as a glucose substitute in solutions for parenteral nutrition. The general characteristics, metabolic properties, and applications of xylitol have been reviewed in [30–36].

Xylitol is found in small amounts in yeast, lichen, and fungi, as well as in a variety of fruits and vegetables [35], [37], [38]. In the human body, xylitol is formed as a normal intermediate of glucose metabolism in amounts of about 5–15 g/d [39].

2.1. Physical and Chemical Properties

Xylitol forms orthorhombic crystals, *mp* 93–94.5 °C, when crystallized from ethanol or methanol [40]. A metastable, monoclinic form, *mp* 61–61.5 °C, has also been described [41]. Commercial, food-grade xylitol has a *mp* of 92–96 °C [42], [43].

Xylitol is very *soluble* in water (122.0 g per 100 g H_2O at 4 °C, 168.8 g per 100 g at 20 °C, 291.3 g per 100 g at 40 °C, and 571.1 g per 100 g at 60 °C) and sparingly soluble in absolute ethanol (1.2 g per 100 g solution at 25 °C) and absolute methanol (6 g per 100 g solution).

Xylitol is optically inactive. The refractive index n_D^{25} of a 10 % aqueous solution is 1.3471 (50 % solution: 1.4132).

Crystalline xylitol has a relatively low *hygroscopicity* (moisture absorption at 60 % R.H. after 4 d at room temperature: 0.051 %). It is stable at temperatures up to its *bp* (216 °C) and does not caramelize.

Aqueous solutions of xylitol have a low viscosity (10 %: 1.23; 20 %: 1.67; 40 %: 4.18; 50 %: 8.04; 60 %: 20.63 mPa · s). The density of a 10 % solution is 1.03 g/mL (20 %: 1.07; 40 %: 1.15; 60 %: 1.23 g/mL).

Xylitol is the sweetest of all polyols (about as sweet as sucrose; see Table 2) and has the highest positive enthalpy of solution (+ 153.1 kJ/kg).

2.2. Production

Xylitol was first obtained by E. Fischer in 1891 as a syrup by reduction of D-xylose with sodium amalgamate. Since the early 1970s, xylitol has

been produced on a commercial scale by *catalytic reduction* of D-xylose with hydrogen in the presence of Raney nickel. D-Xylose is obtained by acid- catalyzed hydrolysis of xylan-containing plant materials such as birch wood, corn cobs, and straw [44]. Since these natural raw materials also contain other carbohydrates, xylitol must be separated from other polyols by chromatographic techniques.

The synthesis of xylitol by *fermentative or enzymatic processes* is also possible in principle. However, such procedures have not been used thus far on a commercial scale. Other routes of synthesis of xylitol are merely of scientific interest [45][46][47].

2.3. Specifications, Analysis, and Legal Aspects

Specifications. Specifications for identity and purity have been laid down by the JECFA [42]. Monographs on xylitol are also included in the Food Chemicals Codex [43] and the U.S. Pharmacopoeia/National Formulary [48].

Analysis. Different methods have been used for the analysis of xylitol in food and biological samples. In most cases, high-pressure liquid chromatography yields the most satisfactory results [49][50][51].

Legal Aspects. Xylitol is approved for use in foods, cosmetics, and pharmaceuticals in more than 40 countries. In the EC, xylitol is included as E 967 in the relevant food additive directives [52]. In the United States, xylitol may be used in foods for special dietary use [53].

In the EC, the calorific value of xylitol is set at 10 kJ/g for purposes of food labeling [54]. This value takes into account the fact that xylitol, like other polyols, is incompletely absorbed [55] (see Chap. 1).

2.4. Uses

Xylitol is used as a bulk sweetener, mainly in noncariogenic confectionery and oral hygiene preparations (toothpaste and mouthwash), and less frequently in dietetic foods (food products for diabetics), pharmaceutical preparations (tablets, throat lozenges, multivitamin tablets, cough syrup), and solutions for parenteral nutrition [36], [56–59]. In noncariogenic confectionery and oral hygiene preparations, xylitol is used mainly because of:

1) Benefits in terms of dental health (xylitol is noncariogenic, inhibits certain caries-causing plaque bacteria (*Streptococcus mutans*), reduces the growth and adhesion of dental plaque, and may favorably affect the balance between de- and remineralization of incipient caries lesions). Regular consumption of xylitol-sweetened confectionery has resulted in significantly reduced increases in caries in several long-term studies of human volunteers [31], [34], [60–63].
2) Organoleptic properties (xylitol is the sweetest polyol and produces a sensation of "freshness" because of its high positive enthalpy of solution [36]).
3) Food-technology properties (relatively low hygroscopicity; good direct compressibility of certain xylitol grades; low melting point, which allows the sinter- coating of pharmaceutical tablets; and relatively high osmotic pressure, which ensures the microbiological stability of products with an aqueous phase) [36], [56], [64].

In solutions for parenteral nutrition, xylitol is used as an alternative energy source (glucose substitute) because of its largely insulin-independent metabolism. In order not to exceed the recommended infusion rate ($\leq 250\,\mathrm{mg\,kg^{-1}\,h^{-1}}$ and $\leq 3\,\mathrm{g\,kg^{-1}\,d^{-1}}$), xylitol is usually administered in combination with glucose, fructose, sorbitol, or lipids [33], [65], [66]. In amino acid solutions for parenteral administration, xylitol is used to adjust the osmotic pressure without the risk of browning (Maillard reactions) during heat sterilization and storage. In contrast to fructose and sorbitol, metabolic intolerance to xylitol is unknown.

2.5. Metabolism, Tolerance, and Safety

Metabolism. Xylitol is absorbed from the digestive tract by passive diffusion. Because of the slow rate of this process, absorption is incomplete (in rats, ca. 20 % [67], see Chap. 1).

The absorbed fraction of xylitol is metabolized mainly in the liver via the pentose phosphate shunt to intermediates of the glycolytic pathway [39]. The nonabsorbed fraction reaches the microbially colonized large intestine, where xylitol is degraded by fermentative processes to absorbable, short-chain fatty acids (mainly acetate, propionate, butyrate) and minor amounts of gas (H_2, CH_4, CO_2) [30], [55].

Tolerance and Safety (see Chap. 1). The safety of xylitol has been assessed by expert national and international groups. On an international level, the JECFA assigned a "not-specified" ADI to xylitol in 1983 [68]. The Scientific Committee for Food (SCF) of the EC arrived at a corresponding favorable decision in 1984 [69].

2.6. Producers

Xylitol is produced mainly in Finland by Xyrofin Oy and in the United States by American Xyrofin Inc.

3. Sorbitol

Sorbitol belongs to the group of naturally occurring hexitols. It was first discovered in 1868 [70] in the berries of the mountain ash in concentrations between 5 and 12 %, and is widely distributed in the flora [71]. The name sorbitol is derived from the scientific name of the mountain ash, *Sorbus aucuparia* L. The fruits of certain rosaceae are especially rich in sorbitol: plums 1.7 – 4.5 wt %, pears 1.2 – 2.8 wt %, peaches 0.5 –1.3 wt %, and apples 0.2 – 1 wt %. In fruit and leaves, sorbitol is formed as a biochemical intermediate in the synthesis of starch, cellulose, sorbose, or vitamin C [72]. In animals, sorbitol can be detected as an intermediate in the absorption of glucose [73] or the formation of fructose via glucose [74]. In 1890, E. Fischer carried out the first chemical synthesis of sorbitol by reducing glucose with sodium amalgamate [75]. The first catalytic hydrogenation was reported by V. Ipatieff in 1912 [76].

Since the 1950s, sorbitol has gained tremendous economic importance throughout the world as a food, sweetening agent, as a stabilizer of humidity, and raw material for other products [77].

3.1. Physical and Chemical Properties

Sorbitol [*50-70-4*], D-glucitol, D-sorbitol, D-glucohexane-1,2,3,4,5,6-hexaol, $C_6H_{14}O_6$, M_r 182.2, has the following structure:

It forms γ-polymorphous, finely crystalline white crystals, that are odorless, freely flowable, and slightly hygroscopic. Sorbitol is also available in the form of water-clear syrup solutions. Sorbitol has a sweet, cooling taste; it has approximately half the sweetness of sucrose. Its physiological calorific value corresponds to that of other sugar alcohols (see Chap. 1).

Solubility. Sorbitol is readily soluble in water (256 g/100 g H_2O at 25 °C); 70 % solutions of sorbitol in water are available commercially but tend to crystallize when cooled to < 10 °C for long periods. Sorbitol is also soluble in dilute acetic acid, methanol, and warm ethanol; it is practically insoluble in organic solvents. The *melting range* of sorbitol is 92 – 96 °C; its *specific rotation* $[\alpha]_D^{25}$ is $-1.9°$ (10 g/100 mL H_2O). The optical rotation of aqueous solutions is increased greatly by the addition of complexing salts (borax, ammonium molybdate): $[\alpha]_D^{20} = +4.0$ to $+7.0°$ (10 g in 100 mL of water, borato complex). *The enthalpy of solution* is +111 kJ/kg (see Table 2). The *bulk density* of instant grades is 40 – 50 g/100 mL and that of crystallized grades 60 – 70 g/100 mL. The equilibrium moisture content is given in Table 3; the density and viscosity of aqueous solutions are listed in Table 4.

Depending on conditions (crystallization from solvents or from the melt), sorbitol crystallizes in several modifications [77], the most stable being the γ-form (*mp* 101 °C).

In neutral media, sorbitol is temperature resistant up to 150 °C and, consequently, bake and boil proof. As a sugar alcohol, sorbitol does not undergo Maillard reactions with amino acids or

Table 3. Equilibrium moisture content of sorbitol

Relative air humidity (26.8 °C), %	30	40	50	60	70	80	90
Water absorption, %	4.0	8.0	12.5	18.0	25.0	33.0	46.0

Table 4. Relative density and viscosity of aqueous solutions of sorbitol

Sorbitol content, %	5	10	25	50	60	70
Relative density	1.014	1.038	1.099	1.198	1.249	1.299
Viscosity, mPa · s	1.230	1.429	1.689	11.09	35.73	185.00

proteins at high temperature (see Chap. 1). Like other hexitols, sorbitol forms chelate complexes with some metal ions (e.g., Fe, Cu, Co, and Ni) in aqueous solution that are stable in the alkaline range [78], [79]. Thus, sorbitol inhibits the prooxidative effect exerted by trace metals in autoxidation (e.g., of fats).

Sorbitol cannot be fermented by yeast. In highly concentrated aqueous solutions (sorbitol content of ca. 50 %), sorbitol prevents the growth of bacteria by osmosis. At low concentration, sorbitol solutions serve as a nutrient medium for bacteria [80]. *Acetobacter xylinium* oxidizes sorbitol enzymatically to give L-sorbose (an intermediate in the synthesis of ascorbic acid). Under dehydrating conditions (action of acid at high temperature), sorbitol loses one molecule of water to form either 1,4-sorbitan (85 %) or 3,6-sorbitan (15 %).

On heating with concentrated sulfuric or hydrochloric acid, a second molecule of water is eliminated with the formation of 1,4: 3,6-dianhydrosorbitol = isosorbide (see Fig. 2).

If sorbitol is kept in aqueous solution for a long period at 170 °C under hydrogenating conditions in the presence of a catalyst in a weakly alkaline reaction, it isomerizes partially to form the isomeric polyols D-mannitol and L-iditol [81]. The hydroxyl groups of sorbitol, sorbitans, and sorbids can be esterified and etherifies with fatty acids; reactions of primary hydroxyl groups predominate [82], [83]. Sorbitol, sorbitan, and partially esterified products react with alkylene oxides (e.g., ethylene oxide) to form polyoxyalkylene derivatives [84].

Figure 2. Anhydride formation of sorbitol

3.2. Raw Materials and Production

Raw Materials. The raw materials of choice for the production of sorbitol are glucose from starch (starting material corn, etc.) [85] and sucrose. The use of sucrose, which must first be subjected to acid hydrolysis to give invert sugar, results in the simultaneous production of mannitol. As renewable resources, both starting materials glucose and sucrose are practically inexhaustible. To produce pure sorbitol grades [86], [87], such as sorbitol powder and sorbitol instant, a highly pure glucose solution is used, which also gives the crystallizing sorbitol solutions [sorbitol liquid, solids content 69 %(min.); sorbitol 91 % (min.) of dry weight].

Noncrystallizing sorbitol solutions [sorbitol syrup, solids content 69 % (min.); sorbitol 50 % (min.) of dry weight]are made from partially hydrolyzed starch syrup [glucose content 50 % (min.)].

Production. The industrial synthesis of sorbitol is based on a process developed in 1925 that involves the catalytic hydrogenation of sugars [88]. Appropriate methods are described in the literature [89], [90]. The microbiological enzymatic production methods mentioned in the research literature use *Zymomonas mobilis* [91–94] and other microorganisms [95], [96], but are not yet economically important.

In catalytic hydrogenation, a ca. 50 % glucose solution, which is made from crystallized glucose, a starch hydrolysate (usually corn starch), or an invert sugar solution, is employed as shown in Figure 3.

Hydrogenation is performed in the presence of supported nickel catalysts (kieselguhr support) or Raney nickel. Two- and more-component catalysts have also been proposed [97], [98]. Industrially, the following processes are employed:

Batch Process. In the batch process [89], 3 – 6 % of catalyst (based on glucose) is suspended in a ca. 50 % glucose solution whose pH has been adjusted to 6. The solution is then hydrogenated with hydrogen in an agitated autoclave at 120 – 150 °C and ca. 70 bar. The time of hydrogenation is 2 – 4 h, depending on the type and amount of catalyst.

Continuous Process. In the continuous process [99–101], a glucose solution, adjusted to pH 6 and containing the catalyst, is passed continuously under hydrogen pressure through reaction tubes connected in series. A constant pressure of 180 bar and a temperature of 150 °C are maintained for a reaction time of ca. 1 h. The continuous process is more economical, but requires strictly controlled hydrogenation conditions. Hydrogenation can also be carried out on a fixed-bed catalyst based on copper oxide –nickel oxide [102] or nickel – titanium [103]. The disadvantage is the relatively short duration of reactivity of the catalyst, but the advantage is a higher-purity sorbitol. With fixed-bed catalysts, hydrolysates of potato starch can also be hydrogenated. After the reaction, the raw sorbitol solution is cooled and freed from catalyst by precipitation and filtration. It is then decolorized with filter acids (e.g., activated charcoal) and demineralized by means of mixed-bed ion exchangers to remove gluconate and nickel ions. The commercial water- clear 70 % *sorbitol solution* is obtained by evaporation of water in vacuum. *Solid sorbitol* is prepared by dehydration un-til a water-free melt is obtained. This melt is cooled and, at the same time, kneaded intensively [101]. The melt is subsequently seeded, and the crystals are removed continuously from the surface (melt crystallization) [104], [105]. Grades of powder with the desired particle size are obtained by grinding.

Instant sorbitol is made by spray drying concentrated aqueous sorbitol solution [106], [107]. Instant sorbitol is readily soluble in water, has a bulk volume that is greater by one-third than powdered sorbitol, and adsorbs finely powdered substances on its microfilament crystalline surface with cross-links in all three spatial directions [108].

In all processes, crystalline sorbitol having the stable γ-form is obtained predominantly [109].

Purity Requirements. The purity of sorbitol grades used for food must meet the requirements of the JECFA [110], the Food Chemical Codex (FCC), and EC guidelines, which largely agree. The methods stipulated here are valid for the determination of purity, and the specifications have also been adopted by pharmacopoeias in most countries.

The following requirements have been stipulated for sorbitol powder: sorbitol content 91 % (min.; based on dry weight), 98 % (min.; dry weight) of sugar alcohols of the general formula $CH_2OH(CHOH)_nCH_2OH$, where n is an integer. The nonsorbitol portion is composed mainly of mannitol [ca. 2 % (max.)], small amounts of other sugar alcohols of the general formula $CH_2OH(CHOH)_nCH_2OH$, where $n > 4$,

Figure 3. Production of sorbitol and mannitol

and minor amounts of hydrogenated oligosaccharides. Maximum concentrations of other constituents are given below:

Water (according to K. Fischer)	1 % (max.)
Reducing sugars (as glucose)	0.3 % of dry weight
Total sugar after hydrolysis (as glucose)	1 % of dry weight
Sulfate ash	0.1 % of dry weight
Sulfate	0.01 % of dry weight
Chloride	0.005 % of dry weight
Nickel	2 mg/kg
Arsenic	3 mg/kg
Lead	10 mg/kg
Zinc	25 mg/kg
Copper and zinc together	50 mg/kg
pH (10 % solution in water)	5 – 7

The same conditions apply to sorbitol liquid and sorbitol syrup.

3.3. Environmental Protection

Sorbitol is a globally approved food additive that is also used like sugars for the production of sweetmeats and diabetic sugar. Consequently, special environmental measures are not required for handling sorbitol. Since sorbitol is also a nutrient for microorganisms, it is microbiologically degradable and does not form hazardous intermediates or final products. In its chemical synthesis, relevant safety regulations must be observed. The collected catalysts are separately regenerated and returned for reprocessing. Unused hydrogen, which is not chemically bound, is recycled. The waste quota produced is extremely small and, therefore, can be neglected.

3.4. Analysis

Several methods are available for the qualitative and quantitative determination of sorbitol [111–115]. The proper isolation of sorbitol from samples, with subsequent purification and enrichment, is important for exact identification. An easy oxidimetric determination is based on the cleavage of C – C bonds with periodate, which is reduced to iodate in the process. In periodate oxidation, 4 mol formic acid and 2 mol formaldehyde are produced [116–118] from 1 mol of sorbitol. This method is not specific and is applicable only when no periodate- consuming accompanying substances are present. TLC [119] permits the separation of other sugars and polyols with lead tetraacetate as the developing agent. The use of GC allows substantially more accurate isolation and quantitative detection [120–123].

A very specific and exact separation can be obtained by means of HPLC [124–128], which is generally the method of choice for quick and safe product control. The enzymatic determination of sorbitol used for clinical analysis has gained acceptance for food analysis although its specificity is doubtful [115], [129–131]. In this reaction, sorbitol is oxidized to fructose by sorbitol dehydrogenase in the presence of NAD. The amount of NADH, which is produced during the course of the reaction is equivalent to the amount of sorbitol present. The NADH absorption is measured at 334, 336 or 340 nm.

3.5. Storage and Transportation

As a result of its hygroscopicity, sorbitol must be packed in tightly closed containers and protected against moisture. Even slight absorption of water causes lumping of the powdered product. In its unopened original packing, solid or liquid sorbitol can be stored almost indefinitely. The usual commercial packs contain a maximum of 50 kg of sorbitol powder or up to 270 kg of sorbitol liquid (barrels). For bulk purchasers, sorbitol can be delivered in big bags, containers, or tank trucks. Sorbitol liquid should not be stored at less than 10 °C for long periods because the resulting crystallization hinders its removal from the container. The maintenance of hygiene regulations associated with food is essential.

3.6. Legal Aspects (see Chap. 1)

In accordance with EC guidelines, sorbitol is a food additive. Consequently, its use in food must be legally controlled by member countries. In view of the harmonization of the Common Market, these regulations should be standardized. According to the German food law, food that contains $> 10\,\%$ sorbitol must carry the label "excessive consumption can produce a laxative effect." In addition, the concentration must be labeled (g/kg or wt %). Further details can be found in relevant national laws.

The use of sorbitol in foods, cosmetics, and pharmaceuticals is approved by law in more than 40 countries. In the United States, the Code of Federal Regulations (21 CFR 184.1835) acknowledges sorbitol as a GRAS substance (generally recognized as safe) and provides guidelines for its use in foods [132], [133].

3.7. Uses

The main consumer of solid and liquid grades of sorbitol is the food industry, followed by the cosmetic and pharmaceutical industries. Sorbitol serves as a moisture stabilizer and softener, sugar substitute, carrier, and general conditioning agent.

Foods. The use of sorbitol in the food industry has many advantages [134–136]. The powdered grades are employed as a sugar substitute for diabetic foods; for sugar-free items such as chocolates, dragées, tablets, chewing gum, and filled hard candy; for reduced- calorie sweetening agents whose sweetness is adjusted with intense sweeteners; and for infusion solutions used in parenteral nutrition. Sorbitol liquid and sorbitol syrup serve as softeners and moisture stabilizers for confectionery of all types [137–140]; marzipan; cakes and pastries; aroma substances; delicacies; mayonnaise and dressings; products made of fish, shrimp, and roe; baking emulsifiers; candied fruits; sauerkraut; natural and artificial skins; ice cream; enzyme preparations; tonics; and tobacco products. The concentration of sorbitol powder used is 10 – 100 %, depending on the food. Sorbitol liquid and sorbitol syrup are

employed in concentrations of 5 – 10 %. For details about special processing technologies, see [135], [136], [141].

Cosmetics. In the production of water-containing cosmetics such as creams, ointments, emulsions, lotions, gels [142–145], and especially toothpastes [146–148], sorbitol syrup is preferred to glycerol. Depending on the desired effect, the concentration required is 3 – 5 % for water stabilization and 10 – 20 % for softening effects.

Pharmaceuticals. Similar to its uses in cosmetic formulations, sorbitol can also be used in pharmaceutical preparations [149–153]. Sorbitol powder has gained acceptance as a tablet excipient [154]. As a result of its surface structure, spray-dried sorbitol is especially suitable for the uniform binding of solid agents. It can be molded directly into tablets without granulation [109], [154–156]. This type of sorbitol is also suited to the production of stable dry suspensions (e.g., with antibiotics [157]) of vitamin tablets [158] or antacid granules [159].

Medical Uses. In medicine, pyrogen-free sorbitol is used in 10 – 20 % solutions, with or without amino acids [160], as infusion solutions for parenteral nutrition [161], especially for diabetic patients [162–166]. It accelerates diuresis in osmotherapy, stimulates cholokinesis in gallbladder and liver diseases [167], and serves as a laxative in enemas administered for constipation.

Technical Uses. In technical applications sorbitol syrup is important primarily as a moisture stabilizer and softener. It prevents the embrittlement of all types of paper [168]; hydrous adhesives and (gelatin-based) glues remain flexible. In the finishing of textiles, leather, and fur, sorbitol serves as a conditioning agent. It also stabilizes the moisture in polyurethane foams [169]. About 25 % of the worldwide production of sorbitol is used in the synthesis of ascorbic acid [170].

Derivatives. Esters of sorbitan [171] with fatty acids (e.g., sorbitan monopalmitate, stearate, laurate, oleate [172], [173], and trioleate) as well as polyoxyethylene derivatives [174] of the general formula:

where R is a fatty acid residue (e.g., palmitoyl, stearyl), are formed from sorbitan by etherification with ethylene oxide, followed by acylation with fatty acid. These substances (e.g., Span, Arlacel, Crill, Tween, and Polysorbate) are important emulsifiers and solubilizers in cosmetic and pharmaceutical products and in the food industry [174], [175]. In sorbitan esters, the lipophilic character predominates, and in polyoxyethylene derivatives, the hydrophilic character [171].

3.8. Physiology, Tolerance, Toxicology

For a general discussion of physiological effects of polyols, see Chapter 1 and [176–183].

The absorption of sorbitol results independent of insulin; an increase in blood sugar level is not detectable in either healthy or diabetic persons. For this reason, sorbitol is an ideal sugar substitute for diabetics [184], [185]. The absorption capacity – orally administered – is 10 – 20 g/h. Metabolism occurs in the liver with the help of sorbitol dehydrogenase via fructose and subsequent glycolysis [176]. No side effects have been observed.

The acute toxicity (LD_{50}, oral) for rats is 17.5 g/kg body weight and for mice 25.7 g/kg. In intravenous administration to rats, the LD_{50} was 7.3 g per kilogram of body weight. Even under extreme conditions, no substance-specific toxic or teratogenic effects could be determined [186], [187]. Earlier suggestion that the oral intake of sorbitol causes cataract formation in the lens of the eye could not be confirmed [188].

3.9. Producers

The most important producers, with commercial products in parentheses, are as follows:

Europe: Roquette, France (Neosorb); Cerestar and Hydrierwerke Rodleben, Federal Republic of Germany and Varallo, Italy (all produce Sorbidex); E. Merck, Federal Republic

of Germany (Karion); Hefti, Switzerland (Sorbex); Cultor-Kotka, Finland; Roche-Dairy, Federal Republic of Germany and United Kingdom; Pet Nitrogen, Hungary; Pliva, Croatia; Vitamine Comp., Commonwealth of Nations.

America. Lonza, ICI, Pfizer, Etichem, and Roche, United States; Atkemix, Canada; Polybasicos, Mexico; Sad Quimica Rhodia, Argentina; Getec, Brazil; Ecuador Polychemics, Ecuador.

Asia. Towa Kasei Kogyo, Nikken, Aito, Takeda, Ajinomoto and Sanei Toka, Japan; Lucky, Korea; San Fu Chemical, Taiwan; Pure Chemicals, Thailand; Sorini, Indonesia.

Africa. Klipfontein Pure Organics, South Africa.

3.10. Economic Aspects

Worldwide production (1992) of sorbitol was estimated at about 650 000 t (calculated as 70 % solution). Of this amount, about 357 000 t (55 %) is accounted for by the sale of 70 % sorbitol solution, including sorbitol syrup, and ca. 20 % is allotted to solid grades of sorbitol (91 000 t). About 25 % of the sorbitol solutions (162 000 t) are used for the synthesis of ascorbic acid. In past years, the increase in demand was, on average, about 3 % per year. Depending on the amounts delivered, the world market price of sorbitol liquid and sorbitol syrup (70 %) is ca. \$ 0.95 –1.40/kg, and the price of solid grades is in the range \$ 1.90 – 2.50/kg. The market value of the sorbitol produced worldwide was at least \$ 900 million in 1993.

4. Mannitol

D-Mannitol is a hexitol derived from D-mannose. D-Mannitol is widely distributed in nature, occurring in olive trees, plane trees, and fruit and vegetables (e.g., pumpkins, strawberries, celery, and onions). It is the main constituent of the ash (*Fraxinus ornus L.*). The air-dried sap of this tree, manna, obtained by heating the bark, contains 30 – 50 % mannitol. PROUST isolated mannitol in the crystalline state from manna [189]. Marine algae, especially brown algae, are also rich in mannitol. They can contain 10 – 20 % mannitol, depending on the time of harvest. Furthermore, a large number of fungi and bacteria can produce this polyol from glucose, fructose, or sucrose [190].

4.1. Physical and Chemical Properties

D-Mannitol [*69-65-8*], mannite, D-mannohexane-1,2,3,4,5,6-hexaol, mannitolum, mannitolo, and manna sugar, $C_6H_{14}O_6$, M_r 182.2 , has the following structure:

Mannitol is a white crystalline powder that is about half as sweet as sucrose. Of the commercially used sugar alcohols, mannitol is the least soluble in water (see Chap. 1, Fig. 1). Because of its positive heat of solution in water (see Chap. 1, Table 2), a cooling sensation occurs when mannitol dissolves in the mouth. This effect is, however, less pronounced than that observed with sorbitol or xylitol.

Mannitol is sparingly *soluble* in many organic solvents (1.2 g/100 mL of ethanol; 5.5 g/100 mL of glycerol), and practically insoluble in ether, ketones, and hydrocarbons. Mannitol has a *mp* of 165 – 168 °C; optical rotation $[\alpha]_D^{25} = -0.48°$ ($c = 7$ g/100 mL). The optical rotation is increased greatly by the addition of borax or ammonium molybdate, and the values become positive (see Table 5). Mannitol has a relative density $d^{20} = 1.52$; the particle-size distribution of crystalline grades is 20 – 250 µm and of granulated grades 100 – 850 µm; its bulk density is 550 – 650 g/L. The viscosities of mannitol and sorbitol solutions are comparable.

Crystalline mannitol is only slightly hygroscopic; appreciable water absorption occurs at > 90 % R.H. Mannitol, like other hexitols, forms chelate complexes with metal ions (e.g., iron, copper, and nickel) in aqueous solution [191]. The iron complexes are especially stable [192]. Even at 150 – 170 °C, mannitol does not react with proteins according to the Maillard reaction. Nitration of mannitol with nitrating acid yields mannitol hexanitrate (hexanitromannitol), which is used as an igniter for detonators and electrical fuses [193]. Like other polyalcohols, mannitol releases water when heated with concentrated sulfuric or hydrochloric acid, giving rise to isomannide (1,4 : 3,6 dianhydromannitol, $C_6H_{10}O_4$). Mannitol cannot be fermented by yeast.

Isomannide

Table 5. Specifications and purity testing of mannitol

Specification	USP XXII	JECFA
Concentration of D-mannitol (based on the dry matter), %	96.0 – 101.5	96.0 – 102.0
Melting range, °C	165 – 169	165 – 169
Specific rotation $[\alpha]_D^{20}$	+ 137 – 145∗	+ 23 – 25∗∗
Loss on drying (105 °C, 4 h), %	≤ 0.3	≤ 0.3
pH		5 – 8
Chloride, %	≤ 0.007	≤ 0.007
Sulfate, %	≤ 0.01	≤ 0.01
Nickel, %		≤ 0.0002
Arsenic, %		≤ 0.0003
Lead, %		≤ 0.0001
Heavy metals (Pb), %		≤ 0.001
Sulfate ash, %		≤ 0.1
Reducing sugar as glucose, %		≤ 0.3
Total sugar as glucose after hydrolysis, %		≤ 1.0

∗ 1 g of mannitol in 10 mL of water after the addition of 4 % ammonium molybdate. ∗∗ 2 g of mannitol in 25 mL of water after the addition of 2.6 g of disodium tetraborate.

4.2. Raw Materials and Production

Production of mannitol by extraction of plant raw materials is no longer economically important. Only in China is mannitol still obtained by acid extraction of marine algae.

Today, mannitol is usually produced industrially (see Fig. 3) from sucrose, after inversion to glucose – fructose syrup (ratio 1 : 1), or from a glucose solution, which is also converted to high-fructose corn syrup (→ Glucose and Glucose-Containing Syrups, Chap. 6.2.) (52 % glucose; 44 % fructose, maltose, and oligosaccharides).

Theoretically, 25 % mannitol and 75 % sorbitol are formed in the neutral pH range from a 1 : 1 D-glucose – D-fructose syrup. Hydrogenation occurs under high pressure in the presence of Raney nickel catalysts. As a result of its lower solubility compared to sorbitol, mannitol is isolated from the concentrated hydrogenation solution by crystallization. The filtrate still contains considerable amounts of mannitol, which can be separated chromatographically [194].

If sucrose is used as starting material and hydrogenation is performed in alkaline solution, mannitol yields of up to 31 % can be obtained [195]. In a pure glucose solution, moreover, D-glucose can be epimerized to D-mannose before hydrogenation by the addition of an acidic solution of ammonium molybdate. Mannose is then hydrogenated directly to D-mannitol [196], [197].

Microbiological processes for the direct production of mannitol from glucose [198], [199] or fructose [200] have been described.

In 1986, the isolation of mannitol from a glucose – fructose syrup was achieved by using mannitol dehydrogenase instead of hydrogenation [201].

Mannitol syrup is not commercially available because of its tendency to crystallize.

The measures that need to be taken for environmental protection, storage, and transport are similar to those taken for sorbitol powder products (see Section 3.5).

Purity Requirements. Mannitol is listed in all the important pharmacopoeias. If used as a food additive, it must meet the requirements of the JECFA [202], the FCC, and the EC guidelines (E 421), which largely agree with each other. The methods for purity testing and the specifications are stipulated in Table 5.

4.3. Analysis

Mannitol can be detected qualitatively by thin-layer chromatography [203], [204].

Three methods are commonly used for quantitative detection of mannitol. The periodometric method [203], [204] is relatively nonspecific, HPLC analysis is very specific [205], and gas chromatography is becoming less and less important.

4.4. Uses

The pharmaceutical industry is the largest consumer of mannitol. Due to its low chemical reactivity and low hygroscopicity, it can be used in the production of tablets as a suitably inert sweet excipient for both organic and inorganic agents.

Normally, granular mannitol is manufactured by the customer; however, directly compressible grades also exist [206]. Granulation can be carried out with or without binder and, if necessary, together with active agents.

Furthermore, mannitol can be used as an osmotic diuretic [207] in the treatment of cerebral edema [208], for reducing intraocular pressure [209], and as a laxative [210].

Mannitol is suitable only for special foods because it exerts a stronger laxative effect than sorbitol, is more expensive and tends to crystallize in water- containing products.

Mannitol is used principally to powder the surface of sugar-free chewing gum; as an admixture to other polyols (sorbitol or xylitol), it is usually employed in concentrations of 5 – 10 %. Furthermore, the quality of hard caramel based on sorbitol or maltitol can be improved by the addition of mannitol. Mannitol is used for powdering and sweetening the surface of diabetic confectionery and other sweetmeats because hygroscopic polyols are unsuitable for this purpose. It is also added to instant dessert powders or polydextrose to reduce hygroscopicity and improve flowability [211], [212].

4.5. Physiology, Tolerance, Toxicology

A general discussion of the physiological properties of sugar alcohols is given in Chapter 1.

When mannitol is administered intravenously, about 80 % is excreted unchanged via the kidneys [213]. Fructose is formed as the first intermediate [214]. Absorption is insulin independent [215], so mannitol is suitable for diabetics.

As a result of slow absorption, the oral intake of single doses > 10 – 40 g can lead to diarrhea caused by osmosis. The threshold value depends on the food consumed together with mannitol [216–218].

Acute Toxicity. LD_{50} = 17.3 g/kg (oral, rat), LD_{50} = 22 g/kg (oral, mouse), and LD_{50} = 17 g/kg (intravenous, mouse). The addition of 2.5 and 5 % mannitol to the food of rats and mice, respectively, for a period of two years showed that mannitol exhibits no carcinogenic properties [219].

4.6. Economic Aspects

Producers: Roquette, France; ICI, United States; E. Merck, Federal Republic of Germany; Fin Sugar, Finland; Gretec, Brazil; Towa Kasei, Kogyo, Japan; Cerestar, Italy; Hefti, Switzerland; Test, People's Republic of China.

Approximately 20 000 t of mannitol was produced worldwide in 1992 at a price of $ 3.75 – 4.75.

5. Isomaltulose and Trehalulose, Isomalt

5.1. Isomaltulose and Trehalulose

Isomaltulose (**1**) (6-*O*-α-D-glucopyranosylfructose [*13718-94-0*]), common name palatinose, and *trehalulose* (**2**) (1-*O*-α-D-glucopyranosylfructose [*51411-23-5*]) are two of the few naturally occurring reducing disaccharide ketoses. Honey can contain both sugars but in low concentrations.

The formation of isomaltulose in the fermentation broth of *Leuconostoc mesenteroides* was first suspected in 1956 [220]. The structure was elucidated in 1957 [221]. The first industrial process for the isolation of isomaltulose was reported in 1972 [222]. The industrial preparation

of trehalulose was described for the first time in 1983 [223]. The sole raw material for the industrial preparation of both sugars is sucrose.

(1)

(2)

Both saccharides belong to the group of glucosylfructoses. However, unlike sucrose, they are reducing carbohydrates.

5.1.1. Physical and Chemical Properties

Isomaltulose crystallizes as the monohydrate, *mp* 123 – 124 °C. The specific rotation is $[\alpha]_D^{20} = +103°$ (calculated on a water-free basis). The tautomeric distribution (20 °C, in water) is 19.7 % of the α-furanose form and 80.3 % of the β-furanose form [224]; the solubility is 0.49 g (anhydrous isomaltulose) per g of water (20 °C).

Trehalulose. The crystallization of trehalulose has not been described until now. The specific rotation of trehalulose in water is $[\alpha]_D^{20} = +50°$ with the tautomeric forms in equilibrium (70.9 % β-pyranose form, 21.1 % β-furanose form, 5.7 % α-furanose form, and 2.3 % α-pyranose form) [224].

On hydrolysis with acids, isomaltulose and trehalulose yield 1 mol each of glucose and fructose. These compounds hydrolyze much more slowly than sucrose (Fig. 4).

On reduction of isomaltulose, the sugar substitute isomalt is obtained [222] (see Section 5.2). The reduction of trehalulose gives an isomeric mixture of 1-*O*-α-D-glucopyranosylsorbitol and 1-*O*-α-D-glucopyranosylmannitol [225].

Figure 4. Hydrolysis of glucosylfructoses in acid solution (10 g/L in 0.1 mol/L HCl, 95 °C)
a) Isomaltulose; b) Trehalose; c) Sucrose

Isomaltulose and trehalulose can be converted to new intermediate products by a number of different reactions. These products are being tested intensively for use in synthesis of new consumer products [226].

5.1.2. Production

The industrial production of isomaltulose and trehalulose proceeds exclusively from sucrose by transglucosidation with the help of immobilized microorganisms that are incapable of propagation.

Isomaltulose. Although a large number of other microorganisms are also capable of forming isomaltulose, *Protaminobacter rubrum* CBS 574.77 is being used for its commercial production. The product composition (% of solids) of an industrial transglucosidation solution is shown below [227]:

Isomaltulose	79 – 85
Trehalulose	8 – 10
Sucrose	0.5 – 2
Isomaltose	1 – 1.5
Oligosaccharides, degree of polymerization ≥ 3	1 – 1.5
Fructose	2.5 – 3.5
Glucose	2.0 – 2.5

Isomaltulose can be obtained in a highly pure crystalline state by multistage evaporative – cooling crystallization.

Trehalulose. Under suitable reaction conditions, trehalulose is produced together with isomaltulose by using *P. rubrum* CBS 574.77 [223].

In addition microorganisms have been found that predominantly form trehalulose directly from sucrose [228].

5.1.3. Uses

Isomaltulose and trehalulose are only partially digested by the bacterial flora of the human mouth. Because of their pure sweet taste, they are being used increasingly, especially in Japan, to replace sucrose, glucose, and fructose in the production of sweets with low cariogenic potential.

However, in contrast to the sugar alcohols, both sugars are fully metabolized, and their use in sweets is restricted because they tend to form reversion and Maillard products. Isomaltulose is used mainly for production of the sugar substitute isomalt.

5.1.4. Economic Aspects

At present, the worldwide production of isomaltulose is ca. 25 000 t and that of trehalulose ca. 3000 t (as syrup with ca. 80 % trehalulose content of the dry substance).

Producers. Südzucker AG Mannheim/Ochsenfurt (Federal Republic of Germany); Mitsui Sugar (Japan).

5.2. Isomalt

Isomalt [*64519-82-0*] is a mixture of the diastereomers 6-*O*-α-D-glucopyranosyl-D-sorbitol (isomaltitol, 1,6-GPS) [*534-73-6*] and 1-*O*-α-D-glucopyranosyl-D-mannitol (GPM; the 1-*O*- and 6-*O*-bound mannitol derivatives are identical because of the symmetry of the mannitol part of the molecule) [*20942-99-8*]. The two isomers are formed in different ratios, depending on reaction conditions for the hydrogenation of isomaltulose [222]. Indeed, 1,6-GPS is also formed in small amounts in the catalytic hydrogenation of starch hydrolysates.

6-*O*-α-D-Glucopyranosyl-D-sorbitol (1,6-GPS)

1-*O*-α-D-Glucopyranosyl-D-mannitol (1,1-GPM)

Both isomers belong to the group of disaccharide alcohols.

5.2.1. Physical and Chemical Properties

6-*O*-α-d-Glucopyranosyl-d-Sorbitol (1,6-GPS). The crystal structure of 1,6-GPS is given in [229]. The melting range is 166 – 168 °C and the specific rotation $[\alpha]_D^{20} = +92.4°$.

1-*O*-α-d-Glucopyranosyl-d-Mannitol (GPM). GPM crystallizes from an aqueous solution as the dihydrate (crystal structure see [230]). The dihydrate releases water of crystallization at 70 – 130 °C. An anhydrous modification is formed that melts at 172 °C. The specific rotation of GPM is $[\alpha]_D^{20} = +91.2°$ (calculated on a water-free basis).

Important characteristics of isomalt are as follows:

Water content	≤ 7 %
Specific rotation	+ 89.8° – + 92.2°
Sintering/melting range	145 – 150 °C
Ash content	≤ 0.05 %
Content of 1,1-GPM or 1,6-GP	each 43 – 57 %
Σ 1,1-GPM + 1,6-GPS	≥ 98 %
Σ D-Mannitol + D-Sorbitol	≤ 1.0

Its solubility in water as a function of temperature is shown in Figure 5.

With a comparable water content (e.g., ca. 2 %), isomalt, in the melt, has a lower viscosity, higher specific heat capacity, and higher boiling-point elevation than sucrose [231]. This indicates that complex formation is much lower and affects its processing technology to a certain extent.

Figure 5. Solubility of GPM, GPS, isomalt, and isomaltulose in water
a) GPS; b) Isomaltulose; c) Isomalt; d) GPM

The components of isomalt are hydrolyzed by acid to give 1 mol each of glucose and sorbitol or mannitol. Compared to sucrose and similar disaccharides, the hydrolysis is clearly slower (see Fig. 6). For this reason, isomalt can be regarded as acid stable in most food applications.

Figure 6. Hydrolysis of isomalt components and sucrose in acid solution (concentration 10 g/L in 0.1 mol/L HCl, 95 °C)
a) GPM; b) GPS; c) Sucrose

Like those of sucrose, the hydroxyl groups of the components of isomalt can be etherified and esterified [232].

5.2.2. Production

On catalytic hydrogenation, isomalt is obtained as an approximately equimolar mixture of the isomers [233]. Industrially hydrogenation is carried out as a fixed-bed process in the presence of nickel catalysts. After hydrogenation and complete deionization, isomalt is obtained as an agglomerate of the two isomalt components by using a specially developed drying process. The agglomerates consist of discrete crystallites of GPM dihydrate, anhydrous GPM, and 1,6-GPS with a primary crystal-size distribution of $< 1\,\mu m$. In processing, agglomerates ca. 0.2–2 mm in size behave like homogeneous crystallites. Since the isomalt components have a high tendency to crystallize (low solubility at low temperature, see Fig. 5), isomalt is sold exclusively as a dry product.

5.2.3. Uses

Because of its pure sweet taste (sweetening power = 0.45 relative to sucrose in ca. 10 % solution), its noncariogenicity, and its low calorific value (0.5–0.6 relative to sucrose), isomalt is almost the ideal sugar substitute for most applications in confectionery. Compared to other raw materials, isomalt is characterized by a low positive heat of solution and very low hygroscopicity (lower than sucrose). In the production of food, isomalt generally does not react with other components of the formulation. Isomalt can usually be processed in plants designed for sucrose as the raw material.

In many countries, isomalt is approved for use in food production. It is classified as a food or food additive, depending on the country. In the United States, acceptance of the application for establishing the GRAS status of isomalt has been published. Its use as a sugar substitute has been confirmed in a large number of publications from virtually all the different product lines in the confectionery industry [234].

Applications in the nonfood sector (e.g., surfactant synthesis and resin production) are also known [232].

5.2.4. Economic Aspects

Isomalt is produced by Südzucker AG Mannheim/Ochsenfurt. Current production is ca. 20 000 t/a.

6. Lactitol

Lactitol was described for the first time by SENDRENS in 1920 [235]. It was produced by KARRER and BÜCHI in 1936 by the reduction of lactose [236]. Today, lactitol is prepared commercially from pure lactose that is as protein free as possible (→ Lactose and Derivatives) by liquid-phase or fixed-bed hydrogenation with Raney nickel catalyst in a continuous or batchwise operation [237]. The conditions are 40 – 50 % aqueous neutral solution, ≥ 100 °C, and ≥ 40 bar. Then the catalyst is separated and the hydrogenated solution is purified by complete deionization with an ion exchanger (→ Ion Exchangers, Chap. 2.2.1.). After multiple-effect evaporation of the purified syrup to a solids content of ca. 75 %, lactitol is isolated by cooling crystallization. Depending on crystallization conditions, lactitol crystallizes usually as the mono- or dihydrate [238], or possibly the trihydrate [239]. Anhydrous lactitol crystals can be obtained only from ethanolic solutions [236], [240].

The specifications for commercially available lactitol monohydrate and lactitol dihydrate are given in Table 5.

6.1. Physical and Chemical Properties

Lactitol [*585-86-4*], 4-*O*-β-D-galactopyranosylsorbitol, 4-*O*-β-D-galactopyranosylglucitol, $C_{12}H_{24}O_{11}$, has a M_r 344.32, *mp* 146 °C, and optical rotation $[\alpha]_D^{25} = +14.40°$.

The density of the crystalline monohydrate is 1.44 g/cm^3; that of the crystalline dihydrate, 1.52 g/cm^3. Both hydrates have an orthorhombic crystal structure that was determined by X-ray diffraction [241].

When lactitol is heated to 170 – 240 °C, it is converted partly to anhydro derivatives (lactitan), sorbitol, and lower saccharides. The formation of lactitan is accelerated by acid (e.g., toluene-*p*-sulfonic acid) [242].

Lactitol is readily soluble in water. For the saturation curve, see Figure 1, Chapter 1; for the enthalpy of solution, see Table 1, Chapter 1. The viscosity of lactitol solutions as a function of temperature is given in [242], [243]. The viscosity of a 64 % aqueous lactitol solution at 20 °C is about 200 mPa · s. The viscosities of lactitol melts have also been determined (e.g., 2.4 Pa · s at 135 °C). For further physical parameters, see [244].

Since the molecule contains no carbonyl group, it is chemically more stable than the corresponding disaccharide (e.g., lactose). The stability of lactitol to alkali is clearly higher than that of lactose. A 10 % solution of lactitol, adjusted to pH 13 with sodium hydroxide solution, can be heated to 100 °C for 1 h without the appearance of discoloration. The stability of lactitol to acids is similar to that of lactose. On heating 10 % solutions to 100 °C for 4 h at pH 1 or 2, 5.6 % or 1.4 %, respectively, of the lactitol is hydrolyzed. No discoloration of the solutions occurs under these conditions. The nine hydroxyl groups of lactitol can be esterified with fatty acids [242]. They react with propylene oxide to form starting materials, e.g., for polyurethanes.

Enzymatic Properties. Enzymatic cleavage of lactitol by β-galactosidases (E.C. 3.2.1.23; → Enzymes) was studied by KARRER and BÜCHI [236]. They found that lactitol is cleaved only with great difficulty. In a patent specification [245], the rate of cleavage was found to be about 10 % that of lactose. More recent results have been published in [246]. The action of β-galactosidase also results in the formation of oligosaccharides (reversion products) [247].

Sensory Properties. The relative sweetness of lactitol is ca. 0.4 compared to that of a 10 % sugar solution and is strongly concentration dependent [248]. The other components of the formulation (matrix) also influence the sensation of sweetness of finished foods containing lactitol. For the enthalpy of solution and the refreshment effect, see Table 1, Chapter 1.

6.2. Physiological Properties

The general comments in Chapter 1 apply to lactitol. Review articles dealing mainly with lactitol

discuss its noncariogenicity [249]; suitability for diabetics [250]; and absorption, tolerance, and reduced physiological calorific value [251].

Lactitol can be used instead of lactulose [*4618-18-2*] (→ Lactose, Chap. 2.1.) for the treatment of hepatocerebral syndrome [252] and chronic obstipation [253].

6.3. Technological Properties

Like sucrose, lactitol is a disaccharide, and it has about the same solubility in water. For this reason, its food manufacturing properties correspond largely to those of sugar. However, the 5 – 10 % water content of lactitol represents the significant difference. It substantially influences processing parameters (e.g., in conching of chocolate) and must be taken into account when developing a formulation. For the use of lactitol in food production, see [242], [243], [254]. Lactitol is employed primarily in making confectionery, chocolates, chewing gum, sweetmeats (e.g., hard boiled candies, fruit-flavored gum, fruit jelly), sugar coatings, dragées, ice cream, and jam, and as a bulking agent for the production of tabletop sweeteners.

6.4. Economic Aspects

Producers of lacticol are: CCA Biochem B. V., The Netherlands; Cultor-Kotka, Finland.

7. Maltitol and Maltitol-Containing Syrups

7.1. Maltitol-Containing Syrups

The development of hydrogenated glucose/ corn syrups, lycasin [*9052-46-7*], goes back to the Swedish starch factory Lyckeby [255]. The composition of hydrogenated products varied according to the composition of the glucose syrup used (→ Glucose and Glucose-Containing Syrups, Chap. 6.). About 50 % of the hydrogenated products were sorbitol and maltitol, and the other 50 % were hydrogenated oligosaccharides with a DP of 3 – 20. Only after standardization of the product composition in the 1980s were these substances approved for use in accordance with food laws. All producers adhere to these specifications (Table 6).

Table 6. Specifications for commercially available lactitol mono- and dihydrate

Specification	Monohydrate	Dihydrate
Appearance	white crystalline powder	
Taste	sweet	
Odor	neutral	
Water content (Karl Fischer method), %	max. 5.5	9.5 – 10.0
Specific rotation $[\alpha]_D^{25}$	+ 14.0 – 14.6	
Melting range, °C	115 – 125	70 – 80
pH, 10 % solution	4.5 – 7.0	
Lactitol content, %	93.5 – 9.60	88 – 90
Mannitol content, %	0.3 (max.)	0.3 (max.)
Sorbitol content, %	0.7 (max.)	0.6 (max.)
Dulcitol content, %	0.2 (max.)	0.1 (max.)
Reducing sugars as glucose, %	0.04 (max.)	0.1 (max.)
Ash content, mg/kg	500 (max.)	
Heavy-metal content, mg/kg	10 (max.)	
Arsenic content, mg/kg	1 (max.)	
Nickel content, mg/kg	1 (max.)	

Table 7. Specifications of hydrogenated glucose syrups and hydrogenated high-maltose syrups

Specification	Hydrogenated glucose syrups	Hydrogenated high-maltose syrups
Trade name	Maltidex 200 Lycasin 80/55	Maltidex 100 Malbit liq.
Solids content, %	75 ± 1	≥ 74
Sorbitol content (solids based), %	6 – 8	2.5 – 3.5
Maltitol content (solids based), %	50 – 55	73 – 77
Maltotriitol content (solids based), %	≈ 10	9.5 – 13.5
Higher polyols, DP * 4 – 20 (solids based), %	≈ 30	6.5 – 14
Reducing sugar as glucose (solids based), %	0.2 (max.)	0.3 (max.)
Ash content, %	0.1 (max.)	0.1 (max.)
Nickel content, mg/kg	1 (max.)	2 (max.)
pH	6 – 7	5 – 7

* DP = Degree of polymerization.

To increase the maltitol content in syrups and, thus, adapt the physical and chemical properties

of the syrups to those of sugar solutions, high-maltose corn syrups (→ Glucose and Glucose-Containing Syrup, Chap. 7.) were hydrogenated [256], and the product composition was standardized (Table 7). Reduction and further processing of the hydrogenated solutions were carried out as described for lactitol (Chap. 6; see also [257]). For both types of syrups, no crystallization occurs even at high solids content. For this reason, they have the same food manufacturing properties in the production of "sugar-free" foods as glucose/corn syrups have in the production of normal foods. Consequently, they are primarily crystallization inhibitors, influencing the texture, moisturizing capacity, and a_w value of low-water foods [258].
